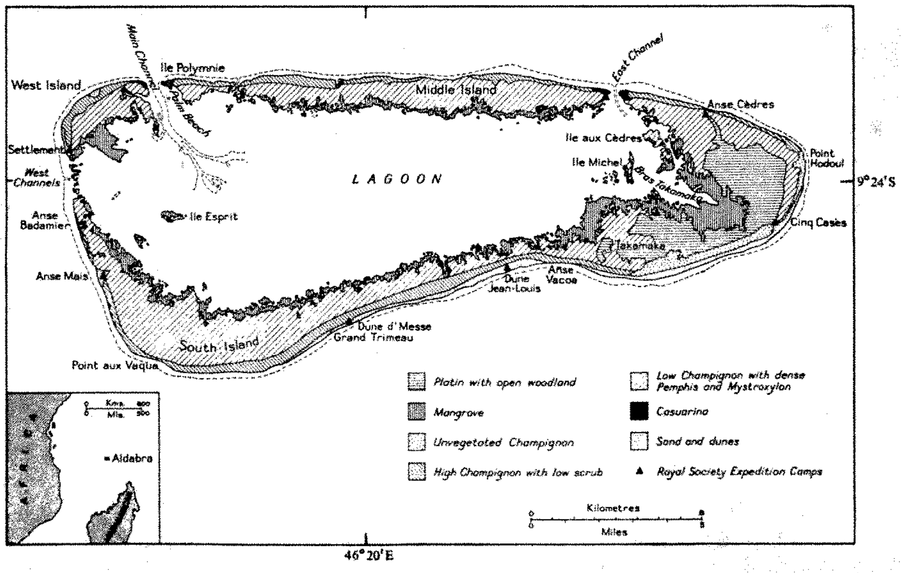
The Aldabra atoll is an oval ring of inhospitable coral divided into four principal islands surrounding a shallow lagoon; it is 34 km long and 14 km wide and lies northwest of Madagascar. The future of the atoll was hotly debated in 1967 when the British government was considering a proposal that it should be developed for defence purposes. The Royal Society, the United States National Academy of Sciences and the Smithsonian Institution all expressed grave concern at the time that such activities would seriously threaten almost the last natural home of the giant land tortoise (*Aldabrachelys gigantea*) and the flightless rail (*Dryolimnas cuvieri*) among other species.

At the end of 1967, the British Government abandoned a plan to build a military airfield and the Royal Society went ahead with its long term research programme which is directed by a committee under Professor T. S. Westoll of the University of Newcastle upon Tyne. The first step was the construction of a research station which was completed in June this year at a cost of £50,000. It includes a laboratory building and accommodation for a permanent staff of four, wives included, and for six visiting scientists. Although the station was principally funded by the Royal Society's grant from the British Government, United States National Academy of Sciences contributed $12,000 for the visiting scientists' accommodation and the World Wildlife Fund donated £2,900 for the purchase of a motor launch. Two-thirds of the £7,500 which the society has paid a Seychelles company for the lease was given by Mr Peter Cadbury but the day to day running of the research activities on the atoll is to be paid for out of its covenant grant. It has been costing about £30,000 a year.

Although the present lease expires in 1985, with the option of renewal for a



The Aldabra atoll.

further twenty years, a spokesman for the Royal Society emphasized this week that the society's interests are chiefly in the scientific research which can be carried out on Aldabra and that after the period of time considered necessary for the completion of the research programme, the society would hand over the lease to a conservation body.

The principal aim of the research is to understand as completely as possible the structure and function of an elevated limestone island ecosystem. Much of the groundwork was carried out during the expedition to Aldabra which the Royal Society mounted in 1967 when there was an imminent danger of extensive changes to the ecosystem. More than sixty scientists have visited the atoll since 1967 and many of these have been supported by the Natural Environment Research Council; the Royal Society, however, maintains its central planning and coordinating role in Aldabra research.

UNITED NATIONS

Doom-Watcher

SUGGESTIONS that the United Nations should play a more vigorous part in dealing with natural disasters have now resulted in a resolution of the Economic and Social Council of the United Nations, adopted at the meeting in Geneva at the end of July, which spells out a few practical steps that might be taken. The resolution will be put forward at the next General Assembly in New York. Its chief proposal is the appointment of a man whose job would be the coordination of disaster relief, at least so far as the various organizations of the United Nations are concerned. The idea is that the disaster relief coordinator should have a small independent office at the United Nations, and that he should be equipped not merely to spend money contributed for disaster relief by governments and other organizations, but also to provide technical assistance and, where appropriate, research on the prevention or at least the prediction of natural disasters of various kinds.

Although the new proposal should go a long way to provide a more easily identifiable centre within the United Nations at which disaster relief could be organized, it falls short of the more ambitious suggestions which have been made in the past that the United Nations should, for example, be equipped with some of the materials which have been shown to be valuable in recent disasters—helicopters chief among them. Instead, the Economic and Social Council has suggested that potential donor governments should let the disaster relief coordinator know in advance what kinds of facilities and services they might be able to provide.

ARCHAEOLOGY

Looting for Museums

from our Archaeology Correspondent

IN the past few weeks, museums and collectors have been alarmed by the discovery of several clever fakes, but in the long run science and scholarship may be more seriously damaged by the increasing flow on to the art market of genuine antiquities derived from illicit excavations. In *American Antiquity* (36, iii ; 1971), Robert Adams, Director of the Oriental Institute in Chicago, writes a strongly worded comment on this situation, stressing the increasing scale of looting and the irreparable loss to archaeology: "If we do nothing, we condone these growing outrages by our silence and jeopardize the international progress of our field".

Gun-running, indeed, is not as profitable these days as antiquity-running. It is true that in many nations of the world (although not yet in Britain), archaeological excavation is illegal unless authorized by the national antiquities service and archaeological finds are automatically the property of the state. Moreover in many Near Eastern countries, as well as in Central America, antiquities may only be exported under an export licence. Unfortunately, however, most of the pieces which now command so high a price in the art markets of the world—the Mexican sculptures, the Greek vases, the Iranian bronzes—have been illicitly excavated and illegally exported.

This is, of course, of serious concern, since the importance of such finds is not simply their intrinsic worth or even their beauty but the information which the circumstances of their discovery can yield about man's past. The archaeological interest of a hoard of gold coins in an earthenware pot, for instance, may be the opportunity it offers for dating the pot and hence of building up a ceramic chronology which in turn allows monuments and other finds to be dated: the gold itself may be secondary. All this and much more is lost in clandestine digging, where the associations are never reliably recorded and all the information obtainable by the use of scientific aids in archaeology goes unremarked.

It is widely and increasingly felt that much of the responsibility for the increasing loss of archaeological knowledge through illicit digging must be borne by those museums and private collectors who pay vast sums for unprovenanced antiquities, with no questions asked. In many cases these august institutions are, in effect, knowingly receiving stolen goods illegally exported from their country of origin. Indeed it is not unknown for Classical statues and vases, found in Greece or Italy, to be deliberately smashed by the diggers so that the pieces may be more conveniently exported than would the complete object, and subsequently reassembled for sale in Switzerland.

The problem has been discussed recently in the context of the "Boston Affair"—not the strangler but the Museum of Fine Arts. The museum, already under a cloud for smuggling into the United States a painting allegedly by Raphael, has also been attacked for obtaining an impressive hoard of prehistoric gold jewellery, obviously from the eastern Mediterranean. The treasure, bought by an anonymous benefactor, is itself regarded by some as at best a collection of unassociated finds put together by an astute dealer and, at worst, a bunch of fakes.

The acquisition rather unexpectedly produced a strong swell of protest in the archaeological world, reported in *Antiquity* (**44**, 88, 171 and 257 ; 1970) in editorials by Glyn Daniel. In a sense, the museum was only doing what many others have done. It is ironical, therefore, that the "Pennsylvania Declaration", a somewhat sanctimoniously worded document from the University of Pennsylvania Museum renouncing the intention of buying unprovenanced antiquity (*Antiquity*, **44**, 171 ; 1970), should come from an institution which only recently bought a comparable treasure in very similar circumstances. Indeed, that hoard of gold jewellery from the east Mediterranean seems more probably genuine than the Boston hoard, and it was recently given authoritative publication in an admirable and scholarly article by Dr George Bass (*American Journal of Archaeology*, **74**, 335 ; 1970). Despite its holier-than-thou attitude, the Philadelphia Museum is right. International legislation is needed and, above all, a real public awareness in the purchaser countries that to buy important unprovenanced antiquities is directly to support looting and the destruction of the past.

Every museum and many private collectors have this sort of skeleton in their cupboards—the Elgin Marbles and the Codex Sinaiticus are British examples. Yet the urgent problem is not so much one of restitution as of stopping the looting. That is why it is right to pillory the unhappy authorities of the Boston Museum.

INDUSTRIAL ARCHAEOLOGY

Through the Past Darkly

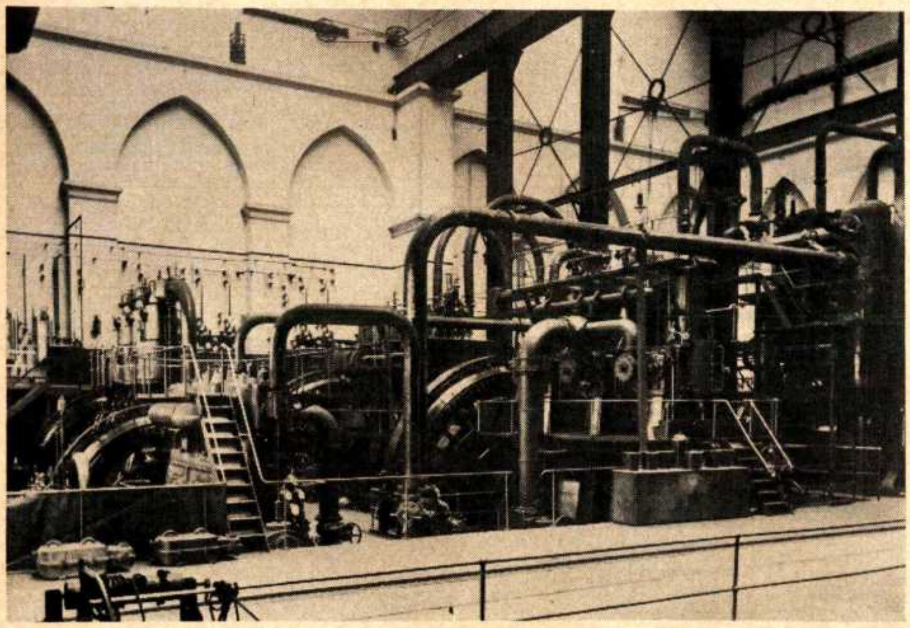
ELECTRICITY'S past may be preserved in a museum. The museum subcommittee of the Electricity Council meets next week and may recommend that a museum should be established. But it is still a matter for debate. Since December last year, Mr J. P. Tanner, formerly manager of the Northern District of the London Electricity Board, has been asking the area boards for details of equipment in their possession that might be of historical interest. The response has been mixed, but most of the boards have appointed somebody to keep in touch with Mr Tanner and the information he wants is beginning to come in.

It is not yet clear if there will be enough equipment worth preserving, but if there is—as seems likely—a museum is not the automatic answer. Would there be sufficient public interest in such a venture to make it worthwhile? Where would it be? And how would it be financed? All these questions need to be answered.

The site problem could be solved by using an old power station. There are several in London, for example, that are being phased out, but clearly only one complete generating plant and assorted smaller items could be displayed in the space available, and to allow for more than one complete plant would require a very large site. And if the museum were to be open to the public, it would have to be easily accessible. But the cost of a large site near the centre of a city could be excessive. An alternative method would be the continuation of Mr Tanner's work of compilation and documentation in considerably greater depth, with detailed descriptions of early power stations and equipment put on record, along with accurate models. Films could be made about old generating plants that are still in use before they are phased out and dismantled.

But the basic question to be resolved is for whom this preservation of gleams from the past is intended—the general public or the specialist. A detailed compact record, with models and film, available to only a limited number of people at any one time, would presumably be a more economical operation than establishing a large and costly museum for a possibly apathetic public. The cost of either project would be high, although the museum would probably prove to be the more expensive of the two, and government aid would almost certainly be needed to make either scheme viable.

At present Mr Tanner is based at the Science Museum where Mr Brian Bowers, keeper of the electrical section is advising him. They are not alone in their work for since March 1965 members of the Institute of Electrical Engineers History of Technology Group have invited interested members to send in record cards of existing historical pieces to the group who collate the information and offer it to museums. Until a full assessment of the equipment available has been made, and a decision taken as to the precise purpose of preservation, the best method of preserving the past cannot be decided.



These Ferranti Alternators (10,000 volt, 1 megawatt), with a 35 foot flywheel ring, and with armature and crankshaft weighing 225 tons, were installed in Deptford Power Station for the London Electricity Supply Corporation at the turn of the century by Ferranti.

Miscellaneous

BRITISH production of both plastic materials for packaging and aerosol cans is expected to increase by about 15 per cent during 1971 compared with an increase of 20 per cent in 1970, according to a review carried out by Pira, the research association for the paper and board, printing and packaging industries. But the market for glass containers is expected to go up only by 2.5 per cent to 6,400 million items. Sales of packaging materials in 1970 were worth more than £900 million of which £180 million was accounted for by tinplate containers and £120 million by plastic materials. Plastic prices reached their minimum in 1969 and in some cases (notably PVC polystyrene) have since begun to rise. All packaging prices increased during 1970.

THE mirror blank for the 3.6 metre telescope of the Meudon Observatory has now been delivered to the French National Institute of Astronomy and Geophysics. After two years of grinding and polishing, the mirror will form the main part of the largest telescope in Europe, probably in the Pyrenees. Although the new telescope will be a little smaller than the Anglo-Australian telescope (144-inch compared with 155-inch) and that to be installed at Cerro Tololo by the Kitt Peak Observatory (158-inch), the French mirror is, like those of these other modern instruments, made from "Cer-Vit", the material with a low coefficient of thermal expansion that has brought telescopes of 300 inches or more within the range of practical propositions.

THE Council for Scientific Policy will be joined for the new term beginning in September by Dr S. L. Bragg, Vice-Chancellor elect of Brunel University, lately a research director at Rolls-Royce. The new recruits also include Dr J. G. Collingwood, director of research at Unilever Limited, and Professor Marie Jahoda, professor of social psychology at the University of Sussex. Professor Jahoda should help to introduce the Council for Scientific Policy to psychoanalytical ways of looking at problems, but it may be of more immediate value that in private life she is married to Mr Austen Albu, MP, long a stalwart of the Labour Party's science policy. After all, as everybody knows, the council will need all the political aid it can muster to help it through the months ahead, when Lord Rothschild's pronouncements may be expected to make up in daring for the way in which the promise of them has helped to justify prevarication in Whitehall.

NSF and NASA get their Money

by our Washington Correspondent

CONGRESS, on the eve of its summer adjournment, has finally approved appropriations for the National Science Foundation and the National Aeronautics and Space Administration. Both agencies are to receive budgets for 1972 which are almost identical to the appropriations asked for by the Administration. The budgets were contained in a bill allotting $18,300 million to the Department of Housing and Urban Development, which was passed by the House on July 29, the Senate on August 3 and signed by President Nixon last week. The bill, which is the fruit of much horse-trading in a conference committee appointed to resolve differences amounting to $224.5 million in the HUD appropriations originally passed by the House and Senate, allocates $622 million to the NSF and $3,298 million to NASA for fiscal year 1972 (which started on July 1). The Administration had requested $623.1 million and $3,301 million respectively for these agencies.

The National Science Foundation can breathe a sigh of relief that the cut of $38 million in its budget recommended by the House Appropriations Committee and approved by the House on June 30 (see *Nature*, **232**, 9 ; 1971), has been more than restored by the conference committee. The House Appropriations Committee, under the chairmanship of Edward P. Boland, suggested a budget of $585 million for the NSF, but the parallel Senate Appropriations Committee set the foundation's budget at $648 million. Predictably, the conference committee opted for a final appropriation midway between the two.

In its passage through the Congressional mill, the NSF's budget request has been under strong attack both from the Science and Astronautics Committee in the House and from the appropriations committees, its chief complaint being the NSF's new programme of "research applied to national needs" (RANN). The Science and Astronautics Committee stripped $30.6 million from the $81 million earmarked for RANN, and redistributed it to the support of institutions and science education. This move was later followed by the House Appropriations Committee, which acidly stated that "the committee will expect the Foundation to utilize the funds included for science education support and institutional support for science as recommended, instead of the diversion of additional funds to basic or applied research", and cut even further the amounts requested for RANN.

The appropriations bill signed last week gives the foundation some $109 million more than it received in fiscal year 1971, most of the increase being $40 million earmarked for picking up basic research projects dropped by other agencies. This item is close to the amount requested by the Administration in its budget application, and its main effect will be to carry on projects that would otherwise have to be abandoned under the terms of the Mansfield amendment which effectively requires the Department of Defense to give up basic research not related to weapon system programmes. Other items included in the appropriations are $99.3 million for science education support, $28.8 million for institutional support of science and $26.8 million for summer institutes and other training programmes for secondary school science and mathematics teachers.

In this year's deliberations over the NSF's budget, the usual Congressional mechanism got itself badly out of step, for the appropriations were passed by both the House and the Senate before the funds had been authorized by Congress. What should happen is that the House Committee on Science and Astronautics and the Senate Committee on Labor and Public Welfare between them set upper limits for the foundation's budget and the appropriations committees then set the final budget levels. This year, however, Congress finally agreed to the authorizations the day after the appropriations were sent to the White House for approval, and the House found itself in the peculiar position of authorizing upper limits for expenditure that had already been appropriated.

The chief reason for this state of affairs was that the House Authorizations Committee set an upper limit of $622 million for the NSF, while the Senate Committee wanted to authorize $706.5 million. The matter was then referred to a conference committee which eventually agreed to set a limit of $655 million. The Senate authorization committee, which was under the chairmanship of Edward M. Kennedy, also recommended that the NSF should receive $907 million for fiscal year 1973, but this was deleted by the conference committee, and in its place was substituted a request that the NSF should provide the Senate Committee on Labor and Public Welfare and the House Committee on Science and Astronautics with a two-year budget projection for fiscal 1973 and 1974.

Although Congress has looked with some disfavour on the NSF's RANN programme, the foundation is pressing ahead with plans to take a closer look at industrial research and in particular at the possibilities for industry/university collaboration in research projects. It has recently appointed a high-level committee under the chairmanship of Mr Jack E. Goldman, vice-president of Xerox Inc, to consider industry/university relations. Initiation of this committee, however, goes back further than the start of the RANN programme, because when Dr William D. McElroy took over the directorship of the NSF in 1969, he proclaimed that more could be done. Dr McElroy began in fact to recruit members for the committee in April, when he sent letters to individuals pointing out that he believes that there is a gulf between the universities and industry which can be bridged with the help of leadership and stimulation from the NSF and inviting them to serve on the committee. Exactly how the committee intends to bridge the gap is as yet unclear, but in view of the harsh words of the House Appropriations Committee on the NSF's stake in applied research, it will clearly have to tread carefully.

Like the appropriations for the NSF, the final appropriations for NASA agreed by Congress fall short of the Administration's request by only a small amount, for the HUD budget that was agreed to last week contained just over $3,298 million for the agency compared with the $3,300 million requested. But in this case the House of Representatives managed to agree on authorizations for the agency two days before it passed the appropriations, and in the Senate, a full six days elapsed between authorization and appropriation. Again, the conference committee which settled the difference between the House and Senate versions of the NASA budget came up with few surprises, for it settled on a budget for the agency almost midway between the House and Senate appropriations, adding $26.5 million to the House bill, but removing $22.6 million from the Senate bill.

There has been some encouragement for the NASA programme for the development of a nuclear powered rocket (the Nerva programme), and $39 million is specifically earmarked for this project. The Administration's budget had set aside only $17 million for Nerva, but even the final appropriation falls short by $11 million of NASA's original budget request. It seems that NASA originally asked for $50 million for Nerva for the financial year now begun. But when told by the Office of Management and Budget to reduce its overall budget request, the agency pared some of the costs of the Nerva programme. The Office of Management and Budget then seized the opportunity to remove all the funding for the project, and eventually agreed under strong pressure from NASA to restore $17 million to keep the project ticking over.

Although the appropriations are not usually broken down into separate figures for each project—only a global sum for research and development, construction and management is given—it seems clear that the conference committee has done well by this shuttle programme. The agency has, to some extent, staked its future on the shuttle, allowing the budget for Nerva and the "grand tour" to be reduced to preserve intact the funding for the shuttle programme, and the Administration's budget request contained $100 million for the programme for fiscal 1972. In spite of a virulent attack on the programme by forces in the senate led by Walter F. Mondale and in the house by Mrs Bella Abzug, Congress authorized $115 million for the shuttle. Also in favour with congress is the Skylab programme, which received an extra $15 million from the authorization committee.

Of the total research and development expenditure authorized by Congress, funding for manned flights is expected to consume some 50.7 per cent—the lowest proportion since 1963—due to the near-completion of the Apollo programme.

NASA's budget for fiscal 1972 represents a decrease of $14.6 million from last year's funding—a drop which was described by Mr Richard Fulton during the house debate on the final appropriations as financially constraining, and likely to lead to cancellation of several potentially rewarding projects. But this did not appeal to Mrs Abzug, who has been seeking for some time to plunge her knife into the NASA budget. She told the house: "There is sad irony in noting that in the same bill providing a total of $3,206,324,000—for that department (HUD), there is also provided a larger amount—$3,271,500,000—for the National Aeronautics and Space Administration. Few more abject demonstrations of our misplaced priorities could be provided".

HIGHER EDUCATION

Straws in the Wind

The Senate went off on holiday on August 6 after doing as much as could be expected of it to win friends among university presidents and faculty. The Senate, like the House of Representatives is looking forward to July 1, 1972, when the legislation now in force and which regulates federal assistance for colleges and universities will expire.

If in due course the Senate is able to reach a satisfactory compromise with the House of Representatives, at present more concerned to help institutions than students, and if, at the same time, it proves acceptable to the Administration, many of whose proposals on higher education have been incorporated into the Senate bill, there is at least a chance that college presidents in the mid-seventies will be able to spend more time on education and less on fund-raising than has been their custom in the recent past. It is, therefore, of some importance that the Administration has let it be known that the $18,000 million that would be spent under the Senate bill in the three years 1972–75 is an "unrealistic" figure and that Senator Warren G. Magnuson, chairman of the Appropriations Committee concerned, has let it be known that the federal budget would not be able to accommodate such a scale of spending "in present circumstances". In fact, what the Senate proposes is a scale of expenditure roughly three times that at present advocated by the Administration, which has just been awarded a total of $1,340 million in the budget for the current year for higher education.

The novel features of the Senate bill are that students would be paid a small stipend—$1,400 a year—and that the institutions which they attend would also receive financial support directly from the federal government. There are also provisions in the bill for supplementary grants to poor students, an echo of the proposal put forward by the Administration. The schemes for student loans at present in force or in preparation would be continued, as would schemes for seeking out particularly students especially likely to profit from higher education. It is also planned that there should be a honeypot of $150 million from which universities and colleges which find themselves in a plight similar to that of the Lockheed Aircraft Corporation could be helped out. The Senate has also agreed with the Administration that there should be set up within the Department of Health, Education and Welfare two new agencies to be known as the National Foundation for Post-Secondary Education and the National Institute of Education. It is just possible that academic enthusiasm for the Senate's action will be moderated, at least in part, by a requirement that students receiving federal support should promise not to use the money for purposes which are not strictly educational. A gallant attempt by Senator Birch Bayh to write into the bill a requirement that women should not be discriminated against in higher education was ruled out of order towards the end of the Senate debate.

On student support, the bill lays down that the basic grant per student shall be either $1,400 or one half the actual cost of attendance at a university, whichever is the smaller. It is also proposed that the amount of the grant should be reduced by the contribution expected to be made by the student's family, calculated on a sliding scale which has yet to be determined but which takes into account such things as the family income, the number of dependents (particularly those in higher education), the capital assets of the student and his family and such unusual expenses as may be occasioned by medical catastrophes. In general, grants will be valid for no longer than four years, but there are exceptions to cater for five-year courses, for supplementary courses and for circumstances in which the amount of money at the disposal of the Department of Health, Education and Welfare is insufficient to meet the demand. The last provision of the Senate bill is held by its supporters to be a device for making sure that the Administration will not be able to skimp on higher education without damaging the cause of poor students to which it professes to be most deeply attached, but the effectiveness of this strategy, attributed to Senator Claiborne Pell, remains to be seen. It is estimated that the total cost of the basic grant programme, will amount to about $1,000 million a year.

There are also schemes in the new bill for helping poor and other deserving students. These supplementary grants will be administered by institutions. The Senate bill proposes that something like $200 million a year will be spent in this way, usually in grants not exceeding $1,000 (except when a student has performed well in the previous academic year). Supplemental grants of this kind will continue for four years or for the duration of an undergraduate course, whichever is the normal practice of the institution concerned. It will be for universities and colleges to select eligible students, but the federal funds available will be shared out among states in proportion to the numbers of full-time students in higher education. The Senate also suggests that $50 million a year should be transferred to states prepared to operate a student incentive grant programme.

NEWS AND VIEWS

New Ways with Volcanoes?

THE article by Dr David R. Waldbaum on page 534 of this issue seems well designed to put a cat among the geological pigeons. One way and another, many of the processes considered to take place within the crust of the Earth entail a marked change of pressure. This is most obvious when volcanic material reaches the surface from a substantial depth beneath it, but it is now clear that transformations of the same kind must occur when material is added to tectonic plates at mid-oceanic ridges and, conversely, when the edges of the plates are re-incorporated into the Earth's crust at subduction trenches. The question that Waldbaum seeks to answer is whether conventional thermodynamics can be used to predict changes of temperature likely to accompany these pressure changes.

It is only fair to say that the issue is exceedingly complicated, not least of all because of the difficulty of defining with sufficient clarity the conditions under which these thermodynamic changes take place. The nub of Waldbaum's conclusion is that there must be many circumstances in which a decrease of the pressure to which some part of the Earth's crust is subjected will be accompanied by an increase of temperature. Such an effect would of course provide a neat explanation of the ways in which igneous material moving upwards towards the surface of the Earth remains molten or at least plastic.

How does all this come about? Waldbaum falls back, quite properly, on a discussion of the application to the materials of the Earth's crust of the Joule–Kelvin effect, best known for its importance in refrigeration processes, when cooling is brought about by the adiabatic throttled expansion of a gas. Liquid CO_2 at ambient temperature can, for example, be converted directly to dry ice at −80° C by this means. For every gas, however, there is at a given pressure an inversion temperature above which throttled expansion results in a temperature increase. (The inversion temperature decreases with increasing pressure.) As Waldbaum points out, the extrusion of a solid substance under similar circumstances will result in a rise in its temperature. In physical terms, the work of extrusion is converted into heat either by direct viscous dissipation or by dissipation as kinetic energy. Since the internal energy of a solid is not strongly dependent on pressure, the heat produced during extrusion must raise its temperature.

It is important to know how closely this chain of argument applies to the processes which go on in the Earth's crust. On the face of things, at least, the pressures within the mantle are great enough to satisfy the interests of most thermodynamicists. Given that the so-called adiabatic gradient for the materials of which the Earth's crust is made may amount to as much as 1 K for each kilobar, it is obviously also possible to think of circumstances in which solid materials are made molten simply by changes of pressure. The chances are, however, that there need to be refinements of the simple picture that suggests itself—the possibility that solids under high pressure at great depths in the crust or mantle could be induced to fly upwards as liquids whenever decreases of pressure took place. Moreover, much depends on whether phenomena such as convection in the mantle, described, for example, by Turcotte and Oxburgh (*J. Geophys. Res.*, **74**, 1458; 1969), can be properly regarded as adiabatic processes. Waldbaum says that even if friction, viscosity and turbulence are ignored in these discussions, the circumstances are such that the ratio $(\partial T/\partial P)_H$ is greater than the ratio $(\partial T/\partial P)_S$, so that the temperature must increase. Where most discussion of Waldbaum's article will be concentrated is on the supposition that these processes are strictly adiabatic or isenthalpic in the sense of the Joule–Kelvin equation.

Only a close definition of what precisely is meant by constant enthalpy—the old-fashioned heat content—is sufficient to resolve the difficulty. Does the definition of the enthalpy of a material include kinetic and gravitational energy, or are these quantities excluded? If the Joule–Kelvin equation should be applied only when changes of gravitational and kinetic energy can either be ignored or compensated for, there is obviously a possibility that the estimates of Joule–Kelvin heating which Waldbaum has made are substantially too great. Obviously it would be valuable to see a closer discussion, along the lines already provided by Mackenzie (*J. Geophys. Res.*, **72**, 6261; 1967) among others of the departures from hydrostatic equilibrium of the pressure differences within convecting regions of the crust and mantle of the Earth. Another difficult, requiring further examination is that there may be many circumstances in which it may be invalid to assume that convection is an adiabatic process. Certainly those parts of the Earth's crust where gravity measurements suggest that convection is rapid are also places at which the heat conduction anomalies are most marked.

For practical purposes, what Waldbaum has predicted is that there will be circumstances in which the process of viscous dissipation within a convecting fluid could result in an increase of temperature in the rising parts of the fluid. This is the hare that thermodynamicists are invited to chase. More immediately, however, it does seem clear that Joule–Kelvin heating of a solid may be important in processes of rapid change as in the impact of meteorites or the effects of seismicity beneath the surface. The process also may be important in the formation and intrusion of kimberlites as well as in violent volcanic eruption. How much more widely applicable may be Joule–Kelvin heating in tectonic processes remains to be seen.

EARTHQUAKES

Control by Explosion

from our Geomagnetism Correspondent

BECAUSE earthquake prediction has proved so intractable a problem, the emphasis within earthquake research has moved strongly towards the possibility of control and modification—a development which was as unexpected as it is exciting. In common with many great scientific discoveries, the idea that major earthquakes might be modified rather than allowed to take their sometimes disastrous course arose "accidentally", though with human help. From the earthquakes which apparently followed the filling of the Hoover Dam during the late 1930s and the disposal of waste chemical and biological weapon materials into a Denver well during the early 1960s there developed the hope that the controlled injection of fluids into regions of tectonic stress might lead to the more gradual release of strain energy. A second possible control mechanism later became apparent when it became clear—chiefly from activities in Nevada—that underground nuclear explosions often lead to the release of energy not derived directly from the explosions themselves. Each of these examples, however, well illustrates the two-sided nature of the strain release phenomenon. The hope that fluid injection and explosions may one day be used to ensure a gradual strain release must be balanced by the fear that less well-regulated experiments could lead to a man-made disaster.

As far as underground nuclear explosions are concerned the best evidence for the interaction between the explosive source and the surrounding rock is the frequent production of horizontally polarized SH and Love waves. Analysis of the radiation patterns of these waves suggests that relaxation of stress leading to the radiation of strain energy takes place around the explosion cavity. The amount of strain energy released and the radius of the relaxation zone have not yet been determined accurately, although from the explosion studies carried out so far it is clear that the energy released in hard rock can be less than the equivalent seismic energy of the explosion itself. The only known, but important, exception was explosion Hardhat (in granite).

Toksöz and Kehrer (*Science*, **173**, 230; 1971) have now taken previous studies further by analysing the surface wave radiation patterns produced by two underground nuclear explosions at the Nevada Test Site, Pile Driver and Greeley, both of which generated Love waves and released considerable strain energy. Pile Driver (58 kton) was detonated in granite and Greeley (825 kton) in zeolitized tuff. Comparison of the results with similar data from other explosions clearly shows that explosions in harder rock (for example, granite) usually release more tectonic strain energy than explosions in soft media such as tuff, alluvium and salt. In the latter cases low rigidities prevent the accumulation of shear strain energy owing to plastic deformation under stress. This is particularly true of salt in which no Love waves are generated at all.

It does not follow, however, that all explosions in a given medium radiate proportionally the same amount of strain energy. Thus in granite, for example, the ratio of the surface wave energy for strain release to the surface wave energy of the explosion itself in the 15 to 22 s range (E_t/E_e) was 13.65 for Pile Driver, 12.00 for Hardhat and only 1.05 for Shoal (western Nevada). It would seem that the magnitude of the pre-existing tectonic stress in the rock is also important—as might only be expected, the E_t/E_e ratio is greater for greater ambient stresses. But tectonic stress and the particular medium seem to be the only two principal parameters involved. Thus Pile Driver and Hardhat, whose sites were only half a kilometre apart, each released strain energy proportional to its own explosive energy. Toksöz and Kehrer conclude, furthermore, that it is the regional tectonic situation which controls the radiation pattern and that the strain energy release arises from close to the explosion and not from earthquakes triggered 10 or more kilometres away. Adjustments at these distances take place gradually as evidenced by the aftershock activity produced by some large explosions.

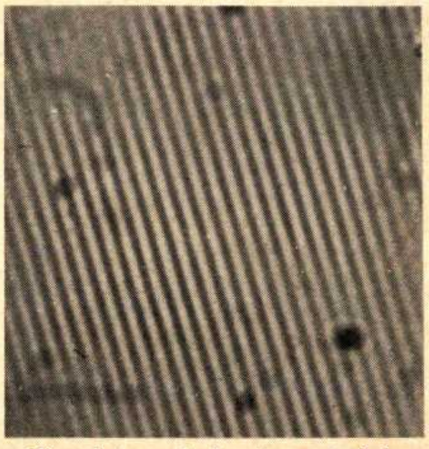
As Toksöz and Kehrer point out, the fact that Pile Driver, Hardhat and, to a lesser extent, Greeley, had high E_t/E_e ratios means that under certain circumstances explosions may be used to release strain energy far in excess of the energy of the explosion itself. The prospects for earthquake modification through artificial strain release are thus encouraging. And because the strain is released from close to the explosion point it would seem that in a practical situation the point of stress reduction could be defined and controlled quite closely. By the same token, however, it would not be possible to deactivate regional stress fields by a single explosion. Nor is it yet known how long it would take for a destressed area to

Lasers, Gratings and Microcircuits

IN next Monday's *Nature Physical Science*, Dr V. I. Little and his colleagues at the Royal Holloway College, London, report another elegant method for producing finely ruled gratings with a laser. Their original method made use of the selective etching of gold from a glass substrate at the antinodes of the electric field associated with the standing light wave in a ruby laser cavity, but they have now discovered the opposite effect—that the condensation of gold vapour onto a glass plate can be selectively inhibited with a periodicity characteristic of the laser standing wave.

During a 50 ns giant pulse from a Q-switched laser, gold is evaporated from a film inside the laser cavity and some of the gold atoms approach a glass collector plate placed at an angle to the axis of the laser and about 0.1 mm from the gold film. Provided that the gold reaches the plate before the laser pulse decays, Little *et al.* find that it only deposited at the nodes of the standing wave and that the pattern generated is similar to that produced by the etching method. The next step in the work will be to devise a system for producing these "modulated" films in a more controlled manner using a continuous standing wave from an argon ion laser.

In the longer term all these techniques could have important consequences for the manufacture of microcircuits and, as well as making modulated gold films, Little's group have been able to deposit dielectric films in a similar way. This opens up the interesting possibility of producing a series of very small capacitors or waveguides, spaced 2.5 μm or so apart, by depositing a dielectric layer between two conducting layers. If the deposition process could be carried out in two laser beams, aligned in such a way that two crossed gratings are formed, then the matrix of rectangular capacitors so produced could be the basis of a cheap and compact electronic memory of storage device.



Microphotograph showing part of the gold pattern.

reaccumulate its original stress. Pile Driver, detonated within half a kilometre of Hardhat but four years later, radiated proportionally the same amount of strain energy as Hardhat. This could mean that the original stress had built up again within four years. The results are inconclusive, however. The yield of Pile Driver was about ten times greater than that of Hardhat and so the volume within which strain was released was correspondingly larger.

But although these results are, in a sense, encouraging, they also have their disturbing aspects. Because the proportional energy release (but not the absolute energy release) is independent of the shot yield, but is instead controlled by the rock properties, a large explosion could release large quantities of tectonic strain energy. A one-megaton explosion with an E_t/E_e ratio similar to those of Pile Driver and Hardhat, for example, would release energy equivalent to a magnitude 6.3 earthquake. A ten-megaton explosion would, under these circumstances, be equivalent to a magnitude 7.2 earthquake. For explosions of these yields hard rock and high tectonic stress are clearly a hazardous combination.

VISNA VIRUS

Oncogenicity Detected

from our Cell Biology Correspondent

At the end of last year and early this year four reports appeared stating that reverse transcriptase, capable of using endogenous viral RNA as well as added synthetic RNAs and RNA.DNA hybrids as templates for DNA synthesis, was present in visna virus and simian foamy virus particles. Until then this enzyme activity had, among viruses, only been detected in the virions of the RNA tumour viruses, where its presence could be explained in terms of Temin's provirus hypothesis of transformation by these viruses.

Reverse transcriptase in two viruses which had never previously been suspected of being oncogenic frayed the edges of an otherwise tidy situation; the sweeping generalization that only RNA tumour viruses contain reverse transcriptase, because only they among the RNA viruses need to integrate their genome into that of their hosts, could no longer be made. But was that really the case? Neither visna virus, which causes a slowly progressing neurological disease of sheep, nor simian foamy viruses, which have not been associated with any known monkey disease, had ever been tested for oncogenicity. So Takemoto and Stone set about remedying that; they are now able to report (*J. Virol.*, **7**, 770; 1971) that visna virus and an antigenically related virus, progressive pneumonia virus (PPV) of sheep, which causes a slowly developing pneumonia and also contains reverse transcriptase as Takemoto and Stone have found, are able to transform mouse cells.

Some three to four weeks after infection with either visna or PPV, cultures of mouse cells (line AL/N and Balb/c 3T3) develop foci of spindle shaped cells from which Stone and Takemoto have established stable transformed lines, which grow rapidly, are not subject to contact inhibition and are tumourgenic for susceptible mice. The medium in which these transformants grew lacked detectable virus, but by cocultivating the transformants with normal sheep testis cells both visna virus and PPV could be rescued; moreover, the rescued virus is identical to virus isolated directly from sheep cells and can be used to transform fresh cultures of murine cells.

To obviate the obvious criticism that some other known oncogenic virus was responsible for the transformation after cells were exposed to these two sheep viruses, Takemoto and Stone tested for antigens of murine sarcoma leukaemia viruses and for T antigens of oncogenic DNA viruses; all the transformed lines gave negative results. Clearly, visna virus and PPV, which have many of the morphological characteristics of RNA

The Mechanism of Phloem Transport

Transport of sugars in plants, from sites of synthesis or food storage to those of utilization, takes place in the phloem through a system of fine tubes—the sieve tubes—which are interrupted at frequent intervals by a series of perforated baffles, the sieve plates. The mechanism by which large quantities of sugar solution are transported at rates which are sometimes in excess of 100 cm per hour is one of the principal unsolved problems of plant physiology.

More than a century has passed since it was suggested by the German botanist, Hartig, that the motivating force for phloem transport is a hydrostatic pressure gradient developed between the source of carbohydrate and its sink. This "pressure flow" hypothesis satisfactorily accounts for many of the features of phloem transport and is still favoured by most plant physiologists today. It has been calculated that the hydrostatic pressure gradients likely to exist are sufficient to induce flow at the rates observed—at least in plants with wide sieve tubes—as long as the pores in the sieve plates are not obstructed.

Much attention has been paid recently to the state of the pores in functioning sieve tubes, but the evidence from electron microscopic studies is contradictory. Sometimes the pores appear open, and in other cases they are clearly blocked. Much seems to depend on the way the material is prepared for microscopic examination, and to confuse the matter further the same observations are interpreted differently by different investigators. Proponents of the pressure–flow hypothesis contend that the pores are normally open but can readily become blocked during preparation of the tissue. Other investigators maintain that the pores in functioning sieve tubes are filled with fibrous membranous structures which somehow assist in transport and that these materials are sometimes displaced leading to the appearance of open pores in sections.

In an attempt to resolve this dilemma, Jarvis and Thaine, of the Grassland Research Institute, Hurley, have been experimenting with new methods of preparing phloem for microscopic observation and they report their observations in next Wednesday's *Nature New Biology*. As an alternative to chemical fixation, the tissue is frozen rapidly while still attached to the plant and sectioned in a cryostat for examination in the light microscope. In material prepared in this way strands with a distinct boundary layer enclosing groups of parallel sub-structures were seen in sieve tubes. The diameter of a strand was similar to that of the sieve pores into which some strands appear to pass. These strands are believed to be the "transcellular" strands reported earlier by Thaine and looked on by some other investigators as artefacts.

There has been a suggestion that the Thaine strands are identical to the slime or P-protein fibres which regularly occur in sieve tubes and seem to be involved in blocking sieve pores in response to wounding. Jarvis and Thaine put forward the idea that slime strands may be constituents of the larger transcellular strands which have been partly degraded.

If, as Thaine believes, the transcellular strands are tubular structures passing through the sieve pores, it is likely that they are the conduits in which longitudinal transport of sugar takes place. Thaine has suggested that the solution is propelled through these tubes by rhythmic contraction and relaxation of protein fibres in the walls. A theoretical analysis of such a peristaltic mechanism has recently been made by Ailkman and Anderson (*Ann. Bot.*, **35**, 761; 1971) and they concluded that the model is a feasible one. The observations of Jarvis and Thaine provide further evidence for the physical reality of transcellular strands on which the hypothesis is based.

tumour viruses and an RNA genome which in size and response to denaturation is remarkably similar to those of the RNA tumour viruses (Lin and Thormar, *J. Virol.*, **7**, 582; 1971), should be grouped with the oncornaviruses. Moreover, Stone and Takemoto's findings, which are fully in keeping with Temin's hypothesis, should spur on the screening of other RNA viruses initially for reverse transcriptase and then oncogenicity if they have the enzyme.

But why do visna virus and PPV contain a reverse transcriptase when they do not apparently cause tumours in their natural host, the sheep? Both are so called slow viruses which chronically infect sheep for many months and even years; both cause very slowly progressing diseases (the parallels with tumour viruses and cancers are obvious enough), and it may well be that the maintenance of slow virus infections depends on the production of a DNA provirus, as does tumour virus infection. As Takemoto and Stone point out, the concept of a DNA provirus should not be overlooked in studies of any slowly progressing disease which has been suspected of having a viral aetiology.

JUPITER

Great Red Spot

from a Correspondent

JUPITER'S Great Red Spot is an unsolved problem of long-standing in astronomy. Nobody to date has produced a satisfactory explanation for the features of this elliptical blemish, although high resolution observations and subtle theorizing are now reducing the number of possibilities.

Observers at the New Mexico State Observatory have photographed Jupiter with a 61-cm telescope on every possible opportunity since 1963, and they can fix the position of the red spot to within 0.2°. A summary of the 1970 observing season prepared by E. J. Reese (*Icarus*, **14**, 343; 1971) gives a good impression of the motions of the surface markings. Last year the red spot was very dark and well defined, and it had mean lateral dimensions of 27,800 km by 13,800 km. There is now considerable information on the detailed motion of the spot, particularly its drift in longitude. In Reese's data the 3-month oscillation discovered five years ago shows up strikingly, with an amplitude of around 1°, and Reese comments that the motion is sufficiently regular for the extreme points of this harmonic motion to be predicted with an uncertainty of only 4 days. Moreover, on longer time scales, the spot probably has a 9-year oscillatory motion, and there is a systematic long term wandering which is aperiodic.

High quality observations such as these are winnowing down the possible models of the red spot, and Carl Sagan, of Cornell University, has recently tackled the problem using propositional calculus (*Comments Astrophys. Space Sci.*, **3**, 65; 1971). His method is to set down a few well established facts with which an acceptable theory must be consistent; these include such properties as the red colouration of the spot, its uniqueness, its periodic longitude excursions and its long term stability. These features are then assembled into a "truth table" or check list for interrogating the theories.

The floating raft hypothesis advanced in 1881 has had a good run; basically it says the red spot is something floating in something else, and is careful not to be too precise. The Jovian raft founders, however, because it cannot really explain the oscillations, and Sagan's table prognosis is decidedly negative. Another class of theories treats the red spot as a meteorological phenomenon. Foremost of these theories is Raymond Hide's Taylor column hypothesis: when a homogeneous fluid flows over an obstacle a relatively stagnant tube of fluid is formed; the red spot is a visible manifestation of a Taylor column caused by a topographical feature on the planet. Sagan's analysis, however, gives this idea a bruising, and he questions how the uniqueness, colour and motion of the red spot can be fitted into such a model.

A novel approach to the problem of the red spot is advocated by W. B. Street, H. I. Ringermacher and G. Veronis (*Icarus*, **3**, 319; 1971). They fuse the attractive parts of the raft and column hypotheses to produce a Cartesian diver model which gives a good account of the mobility of the red spot. In its simplest form the Cartesian diver is an inverted float, containing a small amount of trapped gas, in a jar of fluid. The diver can be made neutrally buoyant at a fixed level by exerting a pressure on the fluid. The Jovian diver is visualized as a light phase of solid hydrogen floating in a dense hydrogen–helium fluid; it lies at depths of several thousand kilometres, in the megabar pressure regime, and its base is heated by the planetary interior. Consequently the diver rises to a higher level, where the lower pressure causes some of the hydrogen to melt. As the solid erodes the bubble of heat is released, and so the Cartesian diver can descend to a lower level and grow again.

Although the argument put forward by Street *et al.* is highly speculative the physical processes behind it are reasonable and they are consistent with the observed changes in the size and colour of the spot over the past century. The value of the hypothesis comes in considering the oscillations, because the equations of motion for a diver in a rotating ocean suggest that the longitudinal motion of the red spot consists of several oscillatory components of different amplitude and frequency. These predictions are in precise agreement with periods derived by Reese *et al.*

Nitric Acid in the Stratosphere

RECENT developments in infrared and submillimetre techniques have led to the identification of several previously unknown molecules in the Earth's atmosphere and stratosphere. But in order to make quantitative determinations of the concentration and distribution of such species it has also been necessary to undertake new laboratory investigations of the molecular vibrational and rotational spectra. The necessary use of long optical paths in infrared observations carries with it the great advantage over chemical probe techniques that local contamination by the observation system can be minimized. Recently Murcray *et al.* (*J. Opt. Soc. Amer.*, **59**, 1131; 1969) detected nitric acid in the stratosphere by studying the near infrared absorption of solar radiation using a balloon at a height of 30 km. The spectra were recorded near sunset to obtain a long path length through the stratosphere, and the minimum altitude observed was about 20 km.

These authors have suggested that the nitric acid is associated with the ozone layer in the upper atmosphere but it is also important to know whether nitric acid is a characteristic constituent of the stratosphere or whether it is accumulating because of pollution in the lower atmosphere. New measurements by Drs Harries, Burroughs and Duxbury (National Physical Laboratory and Bristol University) are reported in the forthcoming issue of *Nature Physical Science*, and these confirm that the nitric acid concentration does indeed decrease with decreasing height as does the concentration of ozone. The new observations are of the submillimetre emission spectrum of the stratosphere observed from a Comet aircraft flying along a controlled path at a height of 12.5 km. At this height there are several important advantages in the emission technique compared with the solar radiation method.

The emission spectrum between 18 and 34 cm^{-1} shows the well known atmospheric emission lines of H_2O, O_2 and O_3 and several unidentified lines. A parallel laboratory study has, however, shown that, although nitric acid has a strong characteristic rotational spectrum in this region, the unidentified lines cannot be attributed to HNO_3.

BARN OWLS

Catching Mice

from our Animal Behaviour Correspondent

BARN owls (*Tyto alba*) can successfully catch mice in total darkness; they rely on the noise the mouse makes as it rustles through leaves to guide them to their prey. R. S. Payne (*J. Exp. Biol.*, **54**, 535; 1971) has demonstrated that the owls can do this even in the absence of other clues as to mouse's whereabouts, such as its smell or the heat given off by its body, and his experiments have shown that the owls are remarkably accurate in both the horizontal and vertical localization of a sound source.

He induced owls to fly towards a loudspeaker that was emitting mouse-like rustles and gauged their accuracy by measuring the distance between the centre of the loudspeaker and the centre of the imprint which the owls' talons made on impact with plasticine surrounding the loudspeaker. This method revealed that the owls seemed to need frequencies above 8.5 kHz, because when these frequencies were removed from the sound source, the birds were much less accurate.

Regardless of its position when it first hears a mouse rustle, an owl always turns to face the mouse and then must have one further sound before it can strike successfully. Payne suggests that this is because the owl localizes a complex sound source by trying to make all frequencies as loud as possible in both ears and would then automatically come to face the source of the sound. To investigate this, Payne placed a microphone in the head of a dead owl at the site of the (now removed) ear-drum and played sounds of constant intensity and frequency through a loudspeaker, recording the response of the microphone as the position of the loudspeaker was varied. In this way, he was able to construct a map of "iso-intensity" lines for each frequency, showing the position of "highs" (places from where the sound was loud) and "lows" in the space surrounding the ear. The owl's sensitivity was found to rise sharply to a maximum along the line of sight. A low in one ear always corresponded to a direction of good hearing for the other ear, and this was interpreted as a special adaptation to sound localization, because it would have the effect of sharpening the frontally directed regions of maximum sensitivity.

Barn owl (photo: Zoological Society of London).

Comparisons of positions at which regions of maximum and minimum sensitivity for a given frequency occurred in the vertical plane revealed that in the right ear such regions are roughly 10–15 degrees higher than in the left ear, presumably as a result of the marked asymmetry of the external ears. A sound which was loud to the right ear could therefore be soft to the left. If the owl then tilted its head in the vertical plane, the relative loudness of the sound in the two ears would change, and this too seems to be an adaptation to reduce ambiguity about the position of a sound.

One of the most characteristic features of an owl, the heart-shaped face, may also be connected with its hearing ability; it may act as a parabolic reflector to catch sound.

Repairing Mispairing of DNA

IN next Wednesday's *Nature New Biology* a simple observation is described which may have profound genetical implications. Using the multicellular alga, *Ulva mutabilis*, Fjeld has produced evidence which lends support to the master-slave hypothesis of undirectional correction of mispairing of DNA and also gives an indication of the reasons for only complete mutations being found after ultraviolet irradiation.

It seems surprising that *Ulva mutabilis* has not been used more frequently for genetic studies because individual cells of this haplo-diplontic alga can be induced to form gametes which will germinate parthenogenetically giving haploid plants. Development starts as a single filament of cells which later becomes tubular, and the characteristic plant form is assumed by elongation of the basal cells to form the stem and the continued division of cells at the apex to form the blade. Chimaeras can be induced by irradiation of young algal germlings and Fjeld has found that there are two kinds which occur in equal numbers; one is genetic so that the gametophytic progeny also show the chimaeric characteristic and the other is merely phenotypic and the gametophytes appear wild type. The chimaeras examined were those with a basal part very like wild type but with a narrow protuberance at the apex which developed into a long ribbon, and those with a bulge somewhere on the blade.

In twenty-six plants with this first type of alteration the apical protuberance did not develop very far, and when the cells of these plants were induced to form gametes the change proved to be merely phenotypic. The apical protuberance on a further twenty-three plants, however, continued development into a long ribbon and analysis of these plants showed that the change in this instance was genetic. Those plants which responded to the ultraviolet light by producing a bulge on the blade also showed the genetic and phenotypic chimaeras to be produced in equal numbers.

It is easy to understand how the genetic alterations can be induced by ultraviolet light, but the nature of the temporary phenotypic alteration is more puzzling, and Fjeld's suggestion that this lies at the level of the gene is interesting. His explanation centres around the fact that only one strand of the DNA is involved in transcription and a mutational event occurring in this strand would be transcribed into an altered mRNA. This cell and any immediate descendants would thus be channelled into an abnormal developmental path giving rise to the chimaeras. Fjeld then goes on to suggest that if the strand which is being transcribed is corrected, using the other strand as template, a phenocopy appears, for all the gametophytic progeny from these cells, in which the abnormal development has been corrected, will be wild type. Up to this point his explanation means that the ratio of genetic to phenotypic chimaeras would be 2:1, for the probability of mutation and correction would be the same in both strands. Half of the mutations in the transcribed strand will thus revert to wild type and will register as phenotypic chimaeras, although if the same type of event occurs in that DNA strand which is not transcribed the mutational event will be unnoticed. Only mutations in this strand which do not revert and which register as genetic chimaeras will be recorded so that there would be an imbalance in favour of genetic changes.

There are many implausible ways of explaining away the discrepancy, but Fjeld's ideas are quite attractive for he chooses to believe that the transcribed strand is always corrected against the other strand but not vice versa. Mutations in the transcribing strand will thus always give rise to the phenocopies, whereas mutations in the non-transcribing strand will produce the true genetic alterations. The expected ratio will then be 1:1.

BACTERIA

The Hot Life

from our Microbiology Correspondent

THE biochemistry of microorganisms able to grow at high temperatures has fascinated biologists for a long time, and the discovery that some bacteria can grow in boiling water (T. D. Brock *et al., J. Bact.*, **107**, 303; 1971) is certain to redouble interest in this area of thermobiology. Brock and his colleagues have been studying for several years the microbiology of thermal springs in Yellowstone National Park and their recent work has centred on Boulder Spring which is fed by two superheated sources. An understanding of the bacteriology of the effluent channel is now beginning to emerge, this particular habitat has a temperature of about 91° C which, at the altitude of Yellowstone, means boiling water.

The bacteria which colonize these inhospitable waters are unknown and have not been cultured in the laboratory, but the elegant techniques which Brock has developed for investigations *in situ* have enabled many of the physiological properties of these organisms to be defined. Brock *et al.* have found, for example, that the generation times of the bacteria last for 3 to 7.5 h at temperatures exceeding 90° C. But their latest study reveals the significant fact that these temperatures are only slightly higher than the optimal temperatures for these organisms.

The technique for determining the environmental optima is very simple. Glass cover slips were suspended in the effluent stream until the colonizing bacteria had formed a dense covering and then the incorporation of various labelled organic substrates was followed in tightly closed vials. The amount of isotope uptake paralleled the amount of bacterial biomass but only occurred if sulphide, or some alternative reduced sulphur compound, was present. The optimal effect was produced with a sulphide level of 13 μg per ml., and although this concentration increased the uptake of all compounds tested, the most dramatic stimulation occurred with leucine, acetate and thymidine (Boulder Spring water itself contains about 3 μg sulphide per ml.). Brock *et al.* conclude that these bacteria can utilize sulphides, sulphite and metabisulphite as energy sources and resemble bacteria like *Beggiatoa* which can incorporate organic matter when reduced sulphur is available. The temperature optimum for isotope uptake stimulated by sulphide ranged from 80° to 90° C, irrespective of the organic substrate, and significant incorporation even occurred at the higher temperature of the stream, 91.5° C.

At least two types of Gram negative bacteria were observed to colonize the cover slips and these could be distinguished by their filamentous or bacillary morphologies. But are the physiological data representative of both bacteria? Autoradiography was unfortunately unable to provide the answer because of the interaction of the sulphide with the photographic emulsion. Although attempts to cultivate these organisms have failed so far, success in this endeavour will be essential to elucidate their peculiar capacity of being able to adapt to boiling water.

ICHTHYOLOGY

Red Sea Migrants

from our Marine Vertebrate Correspondent

ALTHOUGH the Suez Canal is blocked to shipping it is still open as a passageway for fish. Two more Red Sea fishes have been discovered recently on the Israeli Mediterranean coast (A. Lourie and A. Ben-Tuvia, *Israel J. Zool.*, **19**, 203; 1970). One of them, *Pelates quadrilineatus*, is a small, longitudinally striped fish which is found in the coastal waters of the Indo-Pacific region from southern Africa to Australia. It has long been known from the Red Sea but no reports of its occurrence in the Suez Canal are known. This contrasts with the history of the second species, *Crenidens crenidens*, a sea bream which is common in the Red Sea and was reported as early as 1902, within 30 years of the cutting of the canal, as one of the most common fishes in the canal and in the Bitter Lakes, and had reached as far as Port Said. Lourie and Ben-Tuvia, who work at the Sea Fisheries Research Station, Haifa, collected in February 1970 many specimens of *C. crenidens*, up to 15 cm in body length, in a shallow hypersaline lagoon on the northern coast of Sinai.

Other Red Sea immigrants to the Mediterranean have not proved to have such limited habitats and several of the species are common enough to appear regularly in the commercial fish catches of Israel, the Lebanon and Egypt. According to a recent check list of the Mediterranean fishes of Israel (*Israel J. Zool.*, **20**, 1; 1971) by Ben-Tuvia, as many as thirty of the 284 species are immigrants from the Red Sea. The fish fauna of the eastern basin totals only a little more than half of the total of 540 Mediterranean species known, and although this is partly the result of the comparative sparsity of field work and study of critical areas, it is clear that it is a relatively impoverished fauna. Fishes of Red Sea origin have perhaps gained a place in the eastern basin more

RNA.DNA Complexes and Antibody Production

SYNTHETIC hybrid nucleic acids containing DNA and RNA chains are familiar tools of biochemists investigating the properties of various nucleic acid polymerases, and measuring the extent to which natural RNAs hybridize with DNA is a technique widely used by molecular biologists probing gene expression in one cell system or another. But complexes between RNA and DNA which occur naturally in cells have seldom been identified, and for that reason alone the experiments reported by Koros, Koster and Mowery in next Wednesday's *Nature New Biology* will attract considerable interest.

Koros and his colleagues have been investigating the spleen cells of mice, immunized with sheep erythrocytes, which are capable of producing IgM antibodies against sheep red cells and can be assayed *in vitro* by their ability to lyse these erythrocytes. Using an autoradiographic technique they have followed the incorporation by these cells of pulses of ^{3}H-thymidine of ^{3}H-5-uridine. As anticipated, the thymidine label is incorporated into material which can be completely digested by deoxyribonuclease and is therefore almost certainly DNA.

The uridine incorporated by these antibody forming cells, by contrast, responds to digestion by deoxy and ribonucleases in an unusual way. Little if any of the label is removed from the cells by deoxyribonuclease which indicates that little of the uridine can have been converted by the cells to the DNA precursor deoxycytidine. But only about half of the incorporated uridine is digested by ribonuclease, and half the label survives this procedure. If, however, the cells are first digested with deoxyribonuclease and then with ribonuclease all the labelled uridine is digested.

Koros *et al.* believe that these results indicate that in antibody forming spleen cells much of the RNA which is being made remains somehow complexed with DNA and is thereby protected from ribonuclease digestion until, of course, the DNA is digested. Furthermore, they report that spleen cells which are not making antibody incorporate uridine into RNA, 98 per cent of which can be digested by ribonuclease alone. This result, they claim, shows that RNA. DNA complexes are far more abundant in cells making antibody than in similar cells which have not been stimulated to antibody production. As they point out, these DNA.RNA complexes may be involved in antibody synthesis, acting perhaps as messengers, and they are now trying to test this fascinating idea.

Crenidens crenidens.

easily on account of this relative poverty of the native fauna, there being more unfilled ecological niches than there would be in the western basin. Their spread within the present century has, however, been rapid and at least sixteen species must now be regarded as common, some even as far afield as the coasts of Cyprus and Anatolia.

Very little seems to be known about the effects of this influx of Red Sea forms on the native fish fauna. As Ben-Tuvia observes, these fish, and especially the common ones, must be important in food chains and the general biological balance in the area. It may be significant that better than average catches of the immigrant lizard-fish, *Saurida undosquamis,* coincide with years when the native Atlanto-Mediterranean hake, *Merluccius merluccius,* is scarcer than usual. The connexion may not be direct, for *Saurida* and the Red Sea red mullet, *Upeneus moluccensis,* are noticeably more abundant in years of above average temperatures than in cool years in Israeli waters.

It is clear, however, that although this form of biological pollution of the eastern Mediterranean has reached considerable proportions, it is still continuing. With the drastic control exerted by the Aswan dam on the freshwater inflow of the Nile to the Mediterranean further changes in the marine fauna of this area could well take place.

TOXINS

The Perfect Poison

from our Molecular Biology Correspondent

VENOMS, it seems, are frequently more effective than their separated toxins. The ingenious rattlesnake for example, as Hendon and Fraenkel-Conrat (*Proc. US Nat. Acad. Sci.*, **68**, 1560; 1971) now show, secretes a pair of proteins, which act concertedly, one evidently softening up the victim for the other. Crotoxin, as isolated, behaves as a single component in the usual fractionation systems. When, however, amino-groups are chemically modified, an insoluble fraction appears, which is a basic protein, separated from its acidic partner. In ion-exchange chromatography crotoxin separates into two peaks, which, however, seem functionally identical. A tryptic digest of the material from these peaks shows only small differences, suggesting that at least one of the two proteins is heterogeneous, but the acidic and basic components have not separated. In 6 M urea, however, the results are very different, two protein peaks appear of very different amino-acid compositions—one acidic and one basic—eluting at widely different positions. The molecular weights, by detergent gel electrophoresis, are about 8,400 and 13,000.

The acidic protein is not neurotoxic, and does not cause haemolysis, though it is able to cleave lecithin. The basic protein, on the other hand, carries all the haemolytic activity of the venom. Between them the two proteins manifest ferocious neurotoxicity. As Hendon and Fraenkel-Conrat note, enzyme systems that function only when two components are both present are by no means unknown, one subunit species in an oligomer directing the specificity of the other. Alternatively it might be conjectured that lysis of a membrane is necessary before the neurotoxin can go to work.

A rather similar situation has been uncovered by Lowy, Sarmiento and Mitchell (*Arch. Biochem.*, **145**, 338; 1971) in a study of bee venom. This contains a variety of proteinaceous materials, including a hyaluronidase, a phospholipase, and several physiologically active peptides. This package turns out to be lethal to larvae. Lowy *et al.* have purified two peptides—meittin, which is well characterized and has been sequenced, and is the principal component of the venom and one other—and have examined their effects on *Drosophila* larvae. The new peptide is called minimine, for its physiological effect is nothing less than to minimize the insect. Its molecular weight is some 6,000 and it contains cysteine, or cystine. In appropriate doses it does not kill the larvae, but induces a condition of lethargy, in which the effort of feeding seems to be beyond the creature's will-power.

In a second article, Mitchell *et al.* (*ibid.*, 344) report the effects of melittin, which is an oligopeptide of twenty-six residues (molecular weight, 2,800). It is known to possess haemolytic activity, and it now seems that it is also a neurotoxin for the larvae. It is a non-competitive inhibitor of acetylcholinesterase, antagonized by cations—the first case, apparently, of such an effect by a polypeptide.

Cooperation Between Hapten and Carrier *in vitro*

IN recent months, cellular immunologists have been turning their attention to the hapten–carrier. Some of the questions being asked are do B (bone marrow derived) cells and T (thymus derived) cells respond to hapten and carrier respectively, are they specific in their responses, and what are the receptors on the responding cell populations?

An ingenious combination of techniques using *in vivo* and *in vitro* systems has been adopted by Christina Cheers and her colleagues to investigate these problems and they report their results in next Wednesday's *Nature New Biology*. 3.5-Dinitro, 4-hydroxyphenylacetic acid (NNP) was coupled to fowl gammaglobulins (or ovalbumin as a carrier specificity control), and the hapten protein conjugate thus formed was injected into mice, of which the spleens were later harvested. Primed spleen cells in culture in the presence of antigen were shown to be antibody producing by a plaque assay technique using sheep erythrocytes coupled to NNP as target cells for lytic antibody.

In the initial experiments the carrier used for priming *in vivo* and recall *in vitro* was varied, and it was shown that homologous carrier was required to obtain a satisfactory recall response. On the other hand, if cells primed to heterologous carrier were added to cultures in which recall was being attempted by the use of a heterologous carrier–hapten antigen, significant enhancement of the anti-hapten antibody was observed. If either the carrier primed cells or the hapten primed cells were incubated with an anti-immunoglobulin serum there was a marked inhibition of the immune response. The inference here is that both the carrier and hapten primed cells have immunoglobulin-like receptors for the antigens to which they are primed. When combinations of parental and F_1 cells were used in conjunction with specific anti-allosera it was possible to show that the antibody was derived chiefly from the hapten primed cells.

In a further series of experiments Cheers *et al.* injected thymocytes and antigen into irradiated mice. The primed thymocytes were harvested from these animals and were shown effectively to substitute for carrier primed whole spleen cells in enhancing the anti-hapten response of cells primed to a heterologous NNP–protein conjugate.

This whole series of experiments tends to confirm and extend the results of, among others, Raff (*Nature* **226,** 1257; 1970) and his colleagues. There is little doubt that in the fullness of time studies *in vitro* of immune responses in association with the use of cell populations of defined anatomic origins will greatly assist understanding of the nature of immunological responsiveness.

SEAFLOOR SPREADING

Direct Measurement

from our Geomagnetism Correspondent

ON the face of it the direct measurement of the rate of seafloor spreading is an unlikely activity bearing in mind that most of the spreading material is inaccessible, that spreading rates are low and thus that on the oceanic scale the absolute distance of spreading is small even within the human life span. But because of its position astride the mid-Atlantic Ridge Iceland offers a unique opportunity for the direct determination of spreading rate—or at least something closely akin to it—when combined with modern methods of distance measurement. Decker *et al.* (*Science*, **173**, 530; 1971) have now reported the results of just such an experiment to measure the extent of rifting between 1967 and 1970 within the rift zones of Iceland.

During 1967 fifty-eight survey lines, making up a total distance of about 157 km, were measured with a geodimeter. Most of these lines were joined to form two profiles, one across the eastern rift zone and one across the Thingvellir zone, although two, used as calibration lines, lay outside the rift zones in an aseismic area of Tertiary volcanics near the west coast. Seventeen of the survey lines were then remeasured in 1970. A different geodimeter was used here; but systematic errors between the two instruments were resolved by reference to the calibration lines. All of the remeasured lines had apparently increased in length between 1967 and 1970 by distances ranging from 6 to 45 mm. After taking account of an 18 millimetre cross-instrumental difference the lines were found to have lengthened on average by (20 ± 2) millimetres where the quoted error is the standard error of the mean.

The problem with this sort of thing is, of course, that, notwithstanding the sophistication of modern equipment, errors are likely to be large and not easily assessed; and random errors are likely to be particularly troublesome. So how much of the apparent lengthening is random error and how much represents a real extension of the rift zone? Random errors of measurement for eighty repeated observations made in 1967 and for forty-five repeated observations made in 1970 have a normal distribution with a standard deviation of 5.7 mm. Previous experience in California and Hawaii shows such a standard deviation to be reasonable for lines 2 km long ; and this is, of course, much less than the 20 mm average lengthening observed. Moreover, various statistical tests carried out by Decker *et al.* indicated extremely low probabilities for the pattern of extensions from line to line within the profiles to have arisen by chance. Accordingly, the net apparent extension of the eastern rift zone profile between 1967 and 1970 was calculated to be (65 ± 31) millimetres, or about 2 cm a year on average. By contrast, the Thingvellir lines showed an average contraction of 2 mm but this was well within the expected errors of measurement.

Is it possible to use this data to determine the nature of rifting in Iceland? Einarsson (*J. Geophys. Res.*, **73**, 7561 ; 1968) noted the en echelon pattern of rift fractures and related it to shear motions paralleling the rift zones; and in one sense the new data could be taken to support this view. In the eastern rift profile the first three and last lines indicated a net contraction whereas the middle seven gave a net extension (giving an overall net extension). This situation could arise from left-lateral shear movements; but Einarsson had already concluded (*Soc. Sci. Isl.*, **38**, 128; 1967) that the en echelon pattern of fractures near Hekla was caused by right-lateral shear. Einarsson's interpretation and the Decker data are thus inconsistent; and this has led Decker and his colleagues to support the alternative interpretation of Icelandic rifting put forward by Bödvarsson and Walker (*Geophys. J.*, **8**, 285; 1964) in which the rifts are related to crustal extension perpendicular to the strike of the fractures. In this case the measured extension of the eastern rift zone is explicable without complication.

BIOLOGICAL MATERIALS

Standardized Standards

PREPARATIONS of a variety of biological materials are now available free of charge from the National Institute of Medical Research in London, for use as standards to define units of activity or as reference materials. The substances, which are not for human consumption, include angiotensin, antilymphocyte serum and interform, and are available to scientists in any country.

Unambiguous standard units, which define the biological activity of a compound, have been adopted internationally to ensure that experimental results can be meaningfully communicated among research groups throughout the world. Many units can be defined on paper ; for example, enzymatic activity is expressed as the amount of reaction product formed in unit time in precisely described physical and chemical conditions. The activities of other substances, however, cannot be completely characterized by physical and chemical means.

This problem has been overcome by the Expert Committee on Biological Standardization of the World Health Organization, which has established reference preparations for substances used in the prophylaxis, diagnosis and treatment of human and animal diseases, so that their potency can be expressed in uniform terms throughout the world. These preparations are distributed free of charge by the World Health Organization to member countries, and scientists may receive them on request. Further information about this service can be obtained from the WHO International Laboratory for Biological Standards, NIMR, Mill Hill, London NW7 1AA. NIMR also has limited quantities of hormones and antisera, for use in immunoassays, which are available only to people working in the United Kingdom.

These biological standards are intended for calibration, by comparative assay, of the potency of existing national and laboratory standards and are not intended for administration to humans or for general experimental purposes. The list of substances available in reference ampoules ranges widely from pituitary hormones to insulin and immunoglobulins.

Microwave Molecular Line Astronomy

IN next Monday's *Nature Physical Science*, David Buhl and Lewis Snyder describe the techniques and antennae used by the NRAO's group at Green Bank, West Virginia in the study of molecular lines originating in interstellar space at millimetre and centimetre wavelengths. The interstellar environment provides a unique set of "laboratory" conditions with very low temperatures and densities in clouds travelling at high velocity and occupying regions several light years across so that these observations are of interest to chemists and physicists as well as astronomers.

Tiny dust particles in the gas clouds provide surfaces on which chemical reactions can take place, and the discovery so far of twenty-one molecules in space has been a great stimulus to the development of radio astronomy in recent years.

The most exciting aspect of this work has been the discovery of many organic molecules, including those of formaldehyde, hydrogen cyanide and cyanoacetylene, which are of great biological significance. Now the field has developed to such an extent that increased sensitivity from improved instrumentation seems likely to provide the means for the detection of weaker lines and for the resolution of known clouds at frequencies corresponding to the stronger known lines to an accuracy of better than one arc minute.

NRDC and the Environment for Innovation

G. E. HAIGH, A. W. PEARSON & D. S. WATKINS
R & D Research Unit, Manchester Business School

M. GIBBONS
Department of Liberal Studies in Science, University of Manchester

This article describes the historical development in Britain of the National Research Development Corporation, the evolution of its policy and the environment in which it now operates.

In recent years the execution of public policy towards science and technology has been increasingly scrutinized by many, including Parliament. The Parliamentary Select Committee on Science and Technology, for example, recently examined the exploitation of Britain's carbon fibre technology[1], and earlier this year the Secretary of State for Trade and Industry, Mr John Davies, announced that "Mr Docksey, formerly general manager of the Research and Technology Development Department of BP Limited, has agreed to advise me on the arrangements for the exploitation of inventions resulting from public research and the support by the National Research Development Corporation (NRDC) for the development and exploitation of inventions from other sources"[2].

One of the more important changes in the external environment of the NRDC was the outcome of the general election in 1970. The present British Government takes a far less interventionist view of its role than did its predecessor and this has engendered a determination to hive off some of the more commercially oriented activities which government has accumulated over the years. For example, when British Nuclear Fuels Limited was established recently as a wholly owned subsidiary of the UK Atomic Energy Authority (UKAEA), the government stated its intention that at some future date private enterprise would be invited to participate in the equity of the new company[3].

This disengagement has also been demonstrated by government policy on the services to industry which it provides, particularly those of the type previously the responsibility of the Ministry of Technology. Thus the white paper on the reorganization of central government stated of Mintech's successor, the Department of Trade and Industry (DTI): "It will be a major function of the new department, for which special machinery is provided, to review the size and methods of the various services now provided to help industry, in order to determine whether they are a proper charge on the State and, if so, whether the present system of organization is cost-effective and likely to produce the required results or whether other forms of organization would carry out these functions more effectively. These services include . . . government encouragement of industrial research"[4]. One outcome of this new philosophy might be the hiving off of NRDC, which has been functioning during its two decades or so of existence by means of a loan from what is now the DTI, its operating deficit being financed from the public purse. Such a procedure would of necessity entail alteration of the statutes under which the organization now operates. In particular, a way of accommodating (or dispensing with) NRDC's present obligation to act in the national interest would have to be devised; even within organizations which are wholly publicly owned, the problem of catering for the national interest in bodies which are expected to cover their costs on a relatively short term basis is well recognized. Thus the green paper published by the last Labour administration setting out proposals for a British Research and Development Corporation (BRDC) stated "in the civil R & D establishments, despite a rising demand for their services . . . a considerable and deliberate effort has been made to redirect programmes of work towards problems of immediate concern to industry, and likely therefore to bring early benefits to the economy of the country"[5]. Any definition of national interest of course depends on an accurate forecast of the future social and economic needs of the community, one of the problems which the Programmes Analysis Unit (PAU), established at Harwell in 1967, was designed to consider. The proposed BRDC would have brought together the civil research and development laboratories of the UKAEA and those of the then Ministry of Technology under a single management, with the intention that the organization should undertake work for both government and industry on a contract basis. NRDC would have been "assimilated into this new organization so that its expertise in the exploitation of invention would be brought to bear directly on the new corporation's work". (Fears were expressed at the time that this loss of independence might cause NRDC to become little more than a sales organ of BRDC. With the change of government, the BRDC proposals themselves may be deemed to have lapsed, although many of the issues raised in the debate on the green paper are germane to the discussion of any potential alternative organizational forms for government research which the present administration might propose.) Although NRDC's value seems to have been well recognized, however, the area of expertise was not that which had been foreseen when the organization was set up. It is therefore interesting to note the way in which this apparent dichotomy has arisen as a result of changes in both the environment for innovation and the responses of successive governments to meet them[6].

Origins of NRDC

The Second World War ended in an air of general optimism about the possibilities of scientific research and technological development. Nevertheless there was great concern in the United Kingdom that this force for potential good be effectively harnessed in the nation's interest. This concern was focused on four problem areas.

Since the adoption of the Haldane principle of independent research facilities, the government had been responsible for by far the greater part of research expenditure in the United

Kingdom, most of this research being undertaken in the government's own research establishments or in universities. Concentration of effort on specific objectives during the Second World War had accelerated the application of scientific and technological knowledge, techniques and inventions; the peacetime problem was to harness these same activities to industrial needs. Although the Department of Scientific and Industrial Research and the associated government-aided, autonomous industrial research associations (RAs) were active in the application of research to commercial ends, there was no obvious way in which economically valuable research results arising from government-funded research in other institutions could be exploited. Thus a Nuffield College report[7] recognized that "when universities become possessed of knowledge of high commercial value, there is a need for them to secure utilization of such discoveries in the interests of economic progress and the public", whereas there was a tacit acceptance of the fact that universities themselves were both unwilling and incapable of successfully commercializing the results of their research. It seemed obvious that some new form of institution was necessary.

A second area of discontent concerned the operation of the patent system. "From the 1930s there had been a feeling among left wing scientists that private inventions were suppressed by corporate business and finance, and that many inventors would come forward if funds were available to them"[8]. The same Nuffield College report had also expressed the view that the patent system could be used to check invention and exploitation rather than to stimulate it. The Swan Committee Report[9] of 1947 found "no satisfactory evidence of particular examples", but, perhaps influenced by the romantic image of the lone inventor then widely accepted, was "of the opinion that future legislation should be aimed not only at the prevention of 'abuse of monopoly' but also at ensuring the fullest practicable use of the rights conferred by patents towards the development of British production and trade".

The other two areas of discontent were more subjective and chauvinistic. One was voiced by Herbert Morrison in 1944 when he said that "(in the field of scientific research) there is an impression, not without some evidence to support it, that in America and Russia things are happening which we shall do well to emulate. It is generally believed that, in the field of what is called 'fundamental research', British science has as fine a record as that of any country in the world . . . but there is some uneasiness about the application of science to current problems of many kinds, including notably problems of technological development in industry"[10]. This feeling that Britain was good at invention but poor at exploitation was compounded by the case of penicillin, which was seen at this time by some as an example of the exploitation of a fundamental British discovery by foreign competition. Any discussion of the reasons for this foreign application of British inventions leads to an examination of the problems of development and the factors influencing innovation in general; this in fact constituted the fourth principal area of discussion.

Central to the problem was the view that innovation or the commercial application of research results could be modelled as a straightforward linear chain, commencing with the "flowering of the tree of human knowledge"[11]. Although the existence of feedback and the problems of attitude, market needs and so on were noted in passing when delineating this innovation chain through research, development, production and application, the chief preoccupation and concern were with the first stages of research and development. The general acceptance of a simplistic model may have engendered the belief that the efficacy of these various stages could be considered in isolation.

These then were the seminal influences leading the government to announce in 1944 that it was to examine "the need for the establishment of a fund to meet the cost of developing new inventions and of providing facilities for testing new ideas for industry" and how best to integrate this with the existing work of cooperative research associations[12].

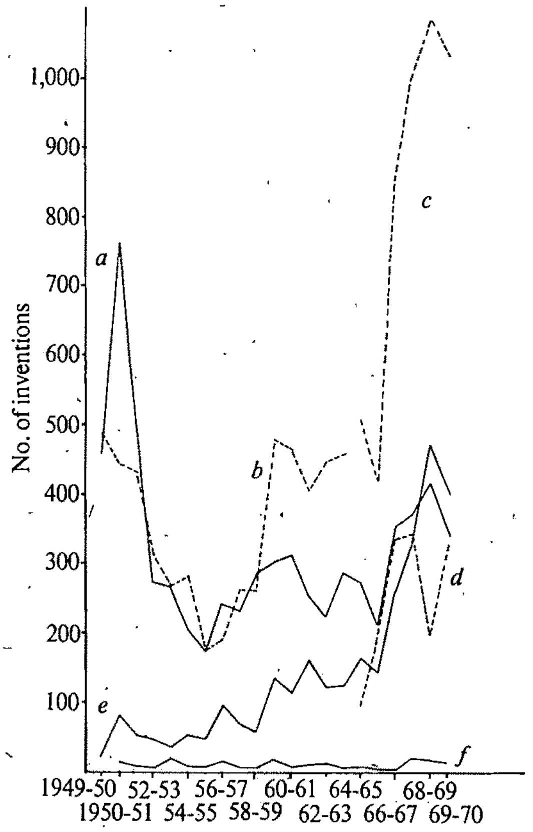


Fig. 1 Number of inventions communicated to NRDC each year (from annual reports). *a*, Research councils and government departments; *b*, total British companies and individuals; *c*, private individuals; *d*, private companies; *e*, universities; *f*, industrial research associations.

Creation of the Corporation

Introducing the Development of Inventions Bill in 1948, the then President of the Board of Trade, Mr Harold Wilson, claimed that the creation of the NRDC "filled an important gap in our scientific and economic life"[13]. The resulting act charged NRDC with (*a*) securing, where the public interest so requires, the development or exploitation of inventions resulting from public research and of any other invention as to which it appears to the corporation that it is not being developed or exploited or sufficiently developed or exploited; (*b*) acquiring, holding, disposing of and granting rights (whether gratuitously or for consideration) in connexion with inventions resulting from public research and, where the public interest so requires, in connexion with inventions resulting from other sources[14].

The NRDC was to operate with an initial loan of £5 million for five years; by securing levies on sales in its exploitation activities, it was hoped that the corporation would eventually be able to balance its accounts by taking one year with another. Its aim was to be commercially minded while endeavouring at all times to consider the national interest. During these early years, the emphasis was primarily on the organization's rôle as an agency concerned with the exploitation of publicly funded research. Consequently NRDC was anxious to establish good liaison with government departments, bodies such as the Medical and Agricultural Research Councils, the universities, and the RAs[15]. The universities and RAs were expected to be fruitful sources of the type of developments which NRDC had been set up to exploit; thus much effort was spent establishing good working relationships with these groups[16].

During its early years of existence, the corporation received large numbers of submissions from private individuals, but its "first five years of experience has failed to confirm that a multiplicity of meritorious private inventors stand in need of public assistance. Overoptimistic hopes of the possibilities of effecting a spectacular increase in the national wealth by supporting them have accordingly been disappointed"[17] (see Table 1).

At this time, NRDC already covered a very wide range of activities from its nurturing of the British computer industry to the development of a potato harvester. Although its continuing concern was with the commercial problems of development and the exploitation and licensing of inventions, it was increasingly recognized that much of the corporation's investment was of a long term nature and, furthermore, was not clearly identifiable with either development or research. Thus in 1954, when the Development of Inventions Act was extended for a further five years, NRDC's research function was clarified, thereby enabling it to support research likely to lead to invention[18].

Table 1 Inventions Considered by NRDC up to 1954

Source of inventions	Total No. of inventions submitted (up to 1954)	Total No. of patent rights assigned for development/exploitation (up to 1954)
Research councils and government departments	2,254	1,322 *
Nationalized industries	5	0
Industrial research associations	45	39
Universities	240	89
Private firms and individuals	1,942	20

* This high take-up rate is chiefly due to the statutory transfer of rights accumulated in previous years.

Industrial Involvement

When the Development of Inventions Act was reviewed in 1958, NRDC's loan ceiling was raised from £5 million to £10 million, and the duration of this advance was extended from ten years to twenty years[19]. By 1960, the corporation's licence income more than covered its administrative expenses, but this was still not sufficient to finance all the development projects which it wished to fund without recourse to this Board of Trade loan. The licence income derived from only 3% of the inventions communicated to the corporation and 9% of the patent rights assigned by the corporation for exploitation[20].

As traditional sources of capital seemed to be reluctant to invest in innovation at the development stage, NRDC felt that it could benefit the nation by encouraging joint development projects with industry.

By 1964, the managing director of NRDC, then Mr John Duckworth, could state that "our experience is that there are good ideas latent in industry which can be brought forward to the stage of cooperative development after a great deal of joint investigation and planning. . . . The projects only materialize when joint investigations are made in the new climate induced by the realization that the risk of financing development work can be shared. Therefore we need a lot of hard work in close cooperation with industry to bring forward projects worthy of support. The 'conventional' development contract approach for projects chosen by government bodies is most unlikely to lead to profitable enterprises, but contracts based on risk sharing with industry on projects selected jointly with industry can have a significant future"[21].

More than one third of NRDC's new projects in 1964 were joint ventures and these covered a very wide field, including automatic foundry equipment, diesel engines and fish finders.

At that time it was felt that NRDC had been most useful "in cases where the fruits of invention had been rather long term, or rather indirect, and therefore not of particular commercial concern"[22,23], so an increase in the corporation's joint development activities with industry was deemed a desirable objective. These factors were borne in mind when the review of NRDC's activities leading to the 1965 Development of Inventions Act was carried out[23].

Stimulating Innovation

The 1965 act was the culmination of a debate about ways in which the corporation's contribution as a stimulus to technological innovation in industry could be increased. In essence, the proposals on which the act was based were those made by the President of the Board of Trade in the former administration, Mr Edward Heath, in 1964. Among other things, the act provided that the limit on the loan to NRDC be increased to £25 million, removed the time limit within which advances to it may be made and decreed that government departments should repay expenditure and/or losses incurred on projects carried out on their behalf by the corporation. It also made changes in NRDC's accountability procedures by empowering the responsible minister to give relief in respect of eight years interest on any advance made to the corporation and permitting him, with Treasury approval, to remit its liability to repay loans corresponding to projects written off by the corporation[24].

The incoming Labour government's proposed drive to modernize British industry was to be spearheaded by greater use of institutions such as NRDC and the RAs and the use of devices such as civil development contracts[25]. This approach was perhaps epitomized by the creation of the Ministry of Technology.

The NRDC, its resources expanded by the 1965 act, reorganized in the belief that "the main part of the corporation's business will continue to be concerned with the support of technological development, but that this will increase markedly and will be more broadly based"[26]. Responsibility for NRDC was transferred from the Board of Trade to the Ministry of Technology, but its operational independence was maintained.

As NRDC's outgoings increased, in large measure through more joint development activities and projects involving increased levels of expenditure, and as its forward commitments became larger, its loan ceiling was soon approached. Increasing exploitation receipts again failed to keep pace with this higher level of activity and NRDC's loan ceiling has since been increased to £50 million.

It would seem, however, that NRDC's own experience after more than twenty-one years and more than 23,000 submissions tends to support the view that "the main reason for the modest scale of NRDC's activities seems simply to be that there are very few inventions worth carrying through the development stage which are not carried through for the want of money"[27].

Changing Environment

—It has already been pointed out that NRDC was formed as a result of the complex interaction of several stimuli, among which the following may be singled out.

—There was no agency to exploit developments resulting from publicly funded research.

—There was a general lack of finance for development activities.

—British research results were being exploited abroad.

—It was felt that the patent system might not be encouraging exploitations of inventions originating with lone individuals in particular.

At the time of NRDC's creation, it was felt that, for some reason, foreigners were often more adept at exploiting the results of British inventiveness than the British themselves. Subsequent studies have shown that the availability of development funds is not of itself sufficient to ensure successful innovation; above all, a clearly identifiable market is essential. Thus in the case of penicillin, which was widely discussed when NRDC was set up, the resources to develop and produce the

Pure Che [illegible]

drug on a large scale were made available only as a result of the intensely felt need for the drug during wartime. It has also been appreciated in recent years that licensing British ideas abroad may itself have an appreciable impact on the balance of trade[28]. To cite one well known example, Pilkingtons now receive as great an income from royalties on the float glass process as from the production of glass itself using this process[29]. In fact NRDC has often been criticized for failing to pursue a more vigorous licensing policy abroad[30].

An important source of the ideas exploited by foreign competitors was believed to be the lone inventor who, it was thought, had no access to sources of development capital and was not well placed to take full advantage of the benefits of the patent system. The NRDC itself recognized at a comparatively early stage that the number of commercially viable ideas being put forward by lone inventors was negligible. Although NRDC is largely associated in the public mind with the exploitation of an invention from a private individual—namely, the hovercraft—both this and the Bacon fuel cell (similarly acclaimed as a great technological achievement) have so far been important net drains on the corporation's resources, chiefly because there does not seem to be a significant market for either invention in this country at the present time.

It was not the lone inventor, but publicly funded research, which was regarded as its principal source of developments when NRDC was created. Although these have been numerically the most significant source, the corporation could recently report, with the benefit of hindsight, that "the inventions acquired from government establishments and other parts of the public sector did not provide significant revenue, and only the emergence of cephalosporin from Oxford University as an important revenue earner in recent years changed this situation"[31]. Cephalosporin has proved to be NRDC's most significant revenue earner by far.

Computer Software

It should not necessarily be assumed from this that little exploitable research is carried out in government and university laboratories[32]; nor does this mean that all such research is exploitable through patent and licensing arrangements. The most obvious example of the last of these types of activity is the development of computer software (which is not patentable) and research in fields such as operations analysis which may not give rise to a definite product. Even in areas where the results are patentable, it does not follow that a separate agency is required to exploit them.

Thus the best way to utilize an area of research expertise (with or without associated patents) may be to create a new organization within the university or government establishment for the specific purpose of exploiting that expertise commercially. Examples of exploitation in this broader sense are the rapid growth in the contract research activities undertaken by government establishments[33], the creation of university-owned companies such as Loughborough Consultants[34] and SWIRL (at Bath University) and the formation of spin-off companies such as Oxford Instruments Ltd and Optel Instruments Ltd by people attempting to exploit their university research expertise directly. Even when it is possible to embody research results in the form of a patent, it could be argued that exploitation activities should be carried out at the level of the innovating institution as is done, for example, by certain of the larger universities or groups of universities in the United States. The cutback in the quantity of real resources available for research may mean that universities and government laboratories will increasingly have to seek this kind of extra income to set against their overheads or subsidize their traditional research activities. And the position of a "middleman" in such situations has recently been the subject of extensive debate following the comments of the Select Committee about NRDC's role in the exploitation of carbon fibres[1], although it could be argued that such a middleman is more insulated from political pressures, as well as being a source of advice.

Two areas in which NRDC has interests at present were not envisaged as its specific concern when it was set up; these are the support of research likely to lead to invention and the support of development within industry—joint development ventures—which have become increasingly important since the 1965 Development of Inventions Act.

In both these areas NRDC was a pioneer and has undoubtedly fulfilled a useful role. But other institutions now exist specifically to fulfil these two functions. The Science Research Council (SRC) recently noted that its objective was to create scientific and technological assets through the support of "research whose timeliness and promise are likely to lead to the discovery of new knowledge and techniques of significant scientific, economic or social benefit"[35]. The SRC recently set up a separate engineering board so that "added point and impetus could be given . . . to encourage . . . the application of high standards of intellectual discipline not only to the furtherance of knowledge, but to its creative development in the best interests of society at large"[36].

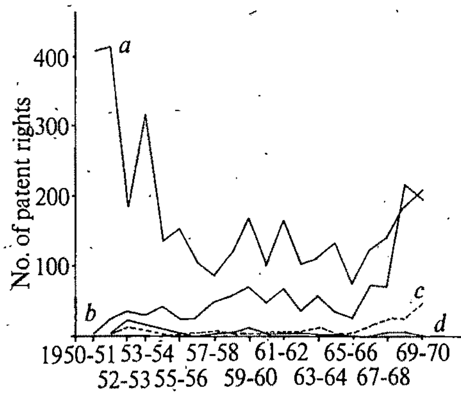

Fig. 2 Patent rights assigned to the corporation each year for further development and/or exploitation. *a*, Research councils and government departments; *b*, universities; *c*, British companies and individuals; *d*, industrial research associations.

As well as providing funds for research likely to lead to commercial exploitation, NRDC has also found it advantageous to participate in the finance of developments in private industry; when the corporation was set up, the possibility that industry itself would be an important source of undeveloped or unexploited new inventions or processes was not then contemplated[37]. This involvement has taken two forms, participation in the "equity in a development" and participation in the equity of the innovating company itself.

In the former case involving a company which is presumably trading profitably, NRDC has been prepared to contribute as much as 50% of the development cost of a particular project with the hope that it will recoup its investment by a levy on sales. (In this respect, NRDC's activities are unique. No other organization in the UK is known to undertake the support of a particular project within a firm in conditions which allow it to recoup its investment only by a levy on sales resulting from the successful outcome of that project. Grossfield[38] has discussed some of the merits of this and alternative systems of project finance.) The advantages of this scheme to the company are two-fold; first, projects can be undertaken on a risk-sharing basis in a situation in which, for one reason or another, the company does not feel it can underwrite the whole cost of development; second, it provides a method whereby a company can undertake development projects over and above those which it could finance from retained earnings or normal borrowing, possibly allowing the firm to broaden its product range more quickly. From the point of view of NRDC the investment is hopefully less risky because the development is carried out within the user company, and possibly more

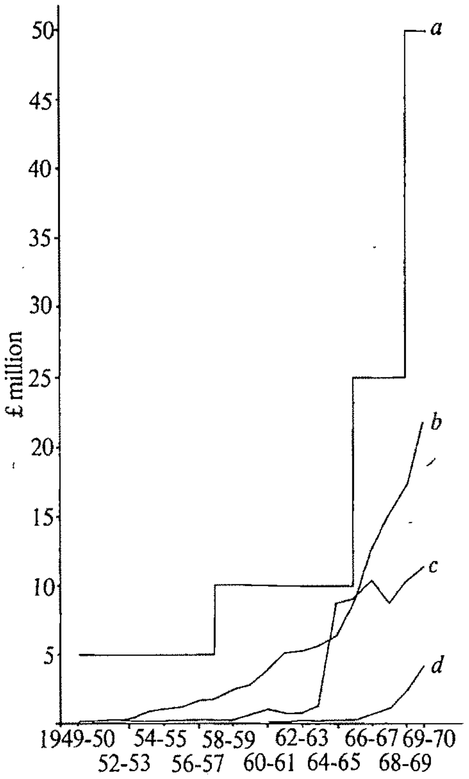

Fig. 3 Finances of NRDC (from annual reports). *a*, Government loan ceiling; *b*, cumulative government loan; *c*, additional forward commitments that year; *d*, total income. The cumulative loan is the difference between total incomings and outgoings. Total income includes sale of patent rights, revenues from exploitation of inventions and levies from joint venture projects.

profitable than some of the corporation's other activities, such as investment in start-up situations.

In the latter case, NRDC takes equity in the associated or subsidiary company—examples include Revenue Systems Ltd (46% holding), which is developing automated credit cards, and Tracked Hovercraft Ltd (100% holding) (see ref. 39 for a complete list). Although NRDC invests in these situations at an earlier stage of development than traditional institutions would usually consider, it presumably adopts very similar investment appraisal, selection and monitoring criteria. Indeed in some cases NRDC has invested in projects jointly with non-government funded institutions; for example, Technical Development Capital Ltd also holds equity in Revenue Systems Ltd.

The development of the NRDC in the context of British scientific and industrial institutions since the end of the Second World War can be seen in terms of a growing awareness of the complexities of technological innovation. It now seems clear that the continual stream of technological development, which forms an important basis for economic growth, cannot be obtained through the simple expedient of nurturing scientific and technical ideas in the hope that their commercial relevance will be apparent to the industrial sector. The temptation is very great to judge an idea or sophisticated gadget on its own merits, without adequate attention to its usefulness and its ultimate commercial viability. With the benefit of hindsight it is now evident that scientific and technical ideas must be seen as one element in the matrix of innovation—more consideration and effort in terms of both money and manpower must be expended in the production and marketing of ideas and hardware.

An apparent paradox, experienced by the NRDC over the last twenty years, thus emerges. On the one hand, there is no doubt that many eventually successful products are dependent on the use of sophisticated technologies and that these should therefore be nurtured; on the other hand, the relationship between technology and the form of organization seeking to exploit it is so intimate that it could draw the government into almost every phase of its operations. In the present political climate, at least, this is regarded as undesirable. The simple fact seems to be that, considerations of national interest apart, it is difficult to see why projects which are judged to be commercially viable should need to be financed from public funds. The difficulty is to ensure that the community does not lose the potential benefits which might arise through innovations resulting from NRDC-type activities which produce a consumer surplus without any organization apparently obtaining any greater or smaller profits[38]. Certainly the government's stated policy of disengagement from industry—witnessed by, for example, the disbandment of the Industrial Reorganization Corporation—is dependent (if industrial development is to continue) on private sources of capital acquiring the same kinds of expertise and taking the same kinds of calculated techno-economic risks that are now being taken by NRDC.

Lithium in Psychiatry

I. B. PEARSON
University Department of Psychiatry, Sheffield S10 3TL

F. A. JENNER
MRC Unit for Metabolic Studies in Psychiatry, University Department of Psychiatry, Sheffield S10 3TL

Lithium salts have been reported to have valuable therapeutic effects in psychiatric disorders. But although some impressive results have been obtained, there is still much to be learnt about the effects and metabolism of lithium.

LITHIUM salts have been used medicinally in various ways for more than a century, and their history has been one of mistaken enthusiasm. Garrod recommended them for the treatment of kidney stones, gout and other rheumatic conditions in 1859[1], but without appreciable success. Subsequently lithium bromide was given as an anticonvulsant in the treatment of epilepsy, but it was no more effective than other bromides. At the end of the nineteenth century lithium salts were first tried in the treatment of mental illness. Lange[2] considered that lithium was helpful in mental depression, but fifty years were to elapse before further and more extensive psychiatric uses developed. More recently lithium salts have been offered as a substitute for sodium chloride in patients requiring a restricted sodium intake, but there were fatalities, and it is now recognized that cardiac and renal decompensation are both indications that the use of lithium should be avoided. Psychiatric interest was revived after work reported by Cade in 1949[3] when, following an accidental observation of a sedative effect on guinea-pigs, lithium was found to be helpful in controlling mania. The modern psychotropic use of lithium dates from that time, but dissemination has been slow and probably reflects a natural caution after the earlier fatalities, combined with the introduction of many new and effective psychoactive compounds.

During the past two decades lithium has been used increasingly in the treatment of manic-depressive illnesses in which the mood of the patient is elevated in mania and lowered in depressions. Results so far suggest that lithium salts have considerable potential in the treatment of manic depressive illnesses, although it is far from clear how they exert their effects.

Very occasionally the patient's mood changes in a regular clock-like manner, but it is more usual to find only occasional brief episodes of mania interspersed in a series of depressive episodes. The remarkably regular patients, though very rare, offer unusual opportunities to prove that lithium salts have a psychopharmacological effect. This has been done, but the relevance of such findings to the more usual clinical studies requires a more complicated statistical approach, taking proper account of the variable natural history of the condition.

It is difficult to classify these illnesses since unipolar affective disorders are much commoner than the bipolar type, and patients who have recurrent episodes of depression for several years may then have a manic episode. Depressions also merge into anxiety and other psychiatric states. The natural history and heterogeneity of the clinical group studied present all sorts of obvious difficulties to the investigator, and it is these types of problem which have influenced much of the debate about lithium in psychiatry. Schou, who produced a useful guide to the literature in 1968[4], has been the most active and assiduous student in this field.

The effectiveness of lithium in the treatment of mania is now well recognized, and has been confirmed by controlled studies. But this treatment requires daily doses of the order of 1.5–2 g of lithium carbonate, when therapeutic and toxic levels closely approximate. In recent years the prophylactic use of lithium has been advocated, using rather smaller doses in the range 0.75 to 1 g daily of lithium carbonate, when toxic effects are reduced. The efficacy of lithium salts in the prophylaxis of manic depressive illness has been the subject of some debate. It has been claimed that when effective, lithium salts diminish the change in mood and in addition reduce the frequency of relapse in affective illness. Angst *et al.*[5] have demonstrated a natural tendency in manic depressive illness for the frequency of episodes to increase, but the pattern of relapse in affective illness is variable, although it does tend to show a progression of increasing frequency which is greater in bipolar illness than in recurrent depressive illness.

Blackwell and Shepherd[6] properly challenged some of the earlier favourable reports, pointing out that with such patients seen at a time of frequently recurring illness, a reduced rate of relapse might be accounted for solely by chance, and certainly this could be so with patients having frequent episodes, even if there is an overall tendency for the cycles to shorten. They suggested that the prophylactic value of lithium could only be determined by a comparative trial. Subsequently several clinical studies have been reported, including double blind trials, and most of them support the original conclusion that prophylactic lithium is of value. In general it seems that the frequency of relapse is appreciably reduced and that the natural trend of increasing frequency is reversed.

Lithium belongs to the group of alkali metals which includes sodium and potassium and it shares several properties with the other members of this group, but Birch has pointed out that in certain respects it resembles magnesium and calcium to which it bears a diagonal relationship in the periodic table[7]. It is absorbed promptly and virtually completely from the gastro-intestinal tract, and this is independent of whether lithium is given as carbonate, citrate or acetate. Lithium is not bound to plasma proteins, but is distributed freely in the tissues, and equilibration occurs, although this is somewhat slower in bone and brain. Distribution in the tissue differs sharply from that of sodium and potassium since lithium is more evenly divided between intracellular and extracellular compartments. Concentrations in the serum reflect those in tissue and can be used satisfactorily to monitor treatment. Lithium salts are largely excreted by the kidneys, and only small amounts are lost in faeces and sweat. Renal lithium excretion is proportional to the plasma concentration over a wide range; renal clearance is of the order of 15–30 ml./min, but decreases with age, and values of 10–15 ml./min are not uncommon in elderly people. Lithium excretion decreases when sodium intake is restricted.

The principal disadvantage of lithium therapy lies in the narrow safety margin between therapeutic and toxic doses. Therapeutic plasma concentrations are usually considered to be between 0.8 and 1.6 mequiv./l.; at these concentrations only minor side effects occur. The commonest of these effects are gastro-intestinal disturbances, muscular weakness, tremor, drowsiness and a dazed feeling. When plasma concentrations are higher, serious toxic effects are liable to ensue, and poisoning results in coma, hyperreflexia, muscle tremor, attacks of hyperextension of the limbs and convulsions; fatalities have occurred. Haemodialysis is the most effective treatment if available but where this is not possible patients should be treated by forced diuresis. Long term treatment may give rise to small goitres and hypothyroidism but these usually respond to modest doses of thyroxine. Teratogenic effects have now been reported in two out of forty patients who received lithium during pregnancy[8]. Clearly lithium should be used with care, and concentrations in the blood should be monitored regularly.

Mode of Action

The mode of action of lithium in affective illness remains obscure, and most theories have related to interference in electrolyte metabolism or to effects on the metabolism of brain amines. More recently evidence has been adduced to suggest a specific effect of lithium on the limbic system of the brain, an area known to be associated with emotion[9]. These uncertainties about the action of lithium reflect the unsatisfactory state of understanding of the biological disturbance associated with manic-depressive illness.

When the fundamental importance of sodium and potassium for neuronal activity is considered together with the similarity of their ions to those of lithium, the suggestion that lithium interferes with the metabolism of these ions seems to be reasonable. Evidence is accumulating that disturbance of electrolyte and water balance accompanies manic-depressive illness although it is not clear whether this is causal or consequential. It has been shown that the administration of lithium leads to changes in the body water spaces, and this observation is supported by the natriuresis following the intake of lithium, which is more striking in normal people than in manic-depressive patients. More lithium is retained by patients than by normal people, and the retention is greater in mania and in patients who respond to lithium therapy. In addition a proportion of patients taking lithium develop persisting polyuria and thirst. This may be explained by the fact that lithium ions specifically and reversibly inhibit the action of the antidiuretic hormone on the kidney. Conceivably the consequences of this inhibition are relevant to the therapeutic effects.

Further work on this particular action has demonstrated that lithium probably blocks the action of the cyclic AMP released by vasopressin[10]. This raises the possibility that inhibition of the effect of vasopressin is just one example of an action on the effects of all hormones releasing cyclic AMP in target cells. In addition to its action on cyclic AMP, lithium also inhibits adenyl cyclase necessary for the production of cyclic AMP from ATP, but in the kidney this only occurs with high doses[11].

Perhaps a more exciting observation is an increase of α-ketoglutaric acid (shown by Bond *et al.*) in the urine of patients receiving lithium. This observation, although unequivocally established, still requires explanation. Does lithium, for example, inhibit enzymes in the tricarboxylic acid cycle and so cause a build-up of α-ketoglutaric acid? Is it a response to alkalosis and does it occur in brain? This, like many other questions, is being actively explored. It could also be relevant to Delgado and DeFeudis's observation[9] that lithium leads to an increased level of brain glutamate.

Inhibition of several enzyme systems could be the result of effects of lithium on tissue magnesium and calcium which have now been observed. As these changes may also occur in brain, possible hypotheses of the consequences are legion.

The work of Smith, Balagura and Lubran[12] demonstrates an apparently direct action of lithium on the lateral nuclei of the hypothalamus. There is stimulates drinking behaviour and presumably thirst. Application of lithium ions directly to the hippocampus and amygdala of monkeys[9] evoked rather specific EEG effects which could be associated with the reduction of aggression reported in man, rodents and fish[13–15]. These are among the few reported direct effects of lithium on nervous tissue, and it is not surprising that neural function can be altered in this way, but the significance of these observations in relation to the therapeutic actions of lithium is not entirely clear.

Lithium does, however, have very clear effects on the electroencephalogram in man. In particular, it increases the amplitude of the alpha rhythm and causes slow waves to appear. After quite usual doses of lithium carbonate have been discontinued, the effects on the electroencephalogram persist for up to 6 weeks.

Lithium, like so many other agents which have therapeutic uses, is like a heavy spanner in a delicate piece of machinery. Like electroconvulsive therapy, it changes so many things that clues to as what is relevant are difficult to assess. Among other effects which require further study, one must include inhibition of carbohydrate transport[16–18] across various membranes including the inhibition of the accumulation of myoinositol by the lens[19] and kidney[20]. The latter substance may well have a special role in the central nervous system.

The most popular current theories suggest that brain monoamine metabolism is altered in manic-depressive illness, but again, as with electrolytes, it is uncertain whether this is cause or effect; moreover, it is not clear which of the amines is related to changes in mood. Lithium has effects on brain monoamine metabolism, but these are confined to noradrenaline and the function of noradrenergic neurones. Noradrenaline metabolism is shifted from O-methylation to intraneuronal deamination with an increase in noradrenaline destruction; noradrenaline uptake by synaptosomes is increased and the release of synaptic neurotransmitters may be inhibited. Unfortunately these findings do not easily fit into models developed to account for the actions of psychotropic drugs, since such drugs change mood in one direction only, whereas lithium restricts mood swing in both directions. One school of thought, however, considers mania as a more profound form of depression[21].

The pharmacological actions of lithium salts are curiously complex, and knowledge about them is far from complete. Indeed, there is ample room for further research designed to increase our understanding of the effects of lithium, which may in turn shed more light on the biological mechanisms possibly involved in manic-depressive illnesses.

Perspectives in Organometallic Chemistry

F. G. A. STONE

School of Chemistry, University of Bristol

Professor Stone describes the state of the art of organometallic chemistry and suggests that it will continue to be a growth point in the chemical sciences.

ORGANOMETALLIC compounds are those substances containing organic groups attached to metal atoms by carbon–metal bonds. The metal may be from the main groups of the periodic table (for example, magnesium or lead), or it may be a transition element such as titanium or iron. The organic groups are of many different types and include both the familiar radicals of organic chemistry such as CH_3 or C_6H_5 which bond both to main group metals and to transition metals, and also stable molecules such as CO, C_2H_4 or C_6H_6 which can coordinate to transition metals. One of the many interesting facets of this field has been the discovery that transition metals can form stable bonds with entities such as cyclobutadiene or trimethylenemethane which are incapable of an independent existence. Countless organometallic compounds are known, and many have played an important role in the history, theory, technology and laboratory practice of chemistry. For example, the discovery[1,2] of ferrocene *bis*(π-cyclopentadienyl)iron, $(\pi\text{-}C_5H_5)_2Fe$ (Fig. 1), brought about a renaissance in the study of organo-derivatives of the transition metals. The elucidation[3] of the polymeric structure of $[(CH_3)_2Be]_n$ did much to stimulate work on electron deficient compounds. In these the number of bonding orbitals exceeds the number of available electron pairs, so that some bonding orbitals embrace more than two atoms—that is, they are multicentred. The Ziegler–Natta catalysts[4] have had a profound effect on the technology of macromolecules, and organoboron compounds are now widely used in organic syntheses[5].

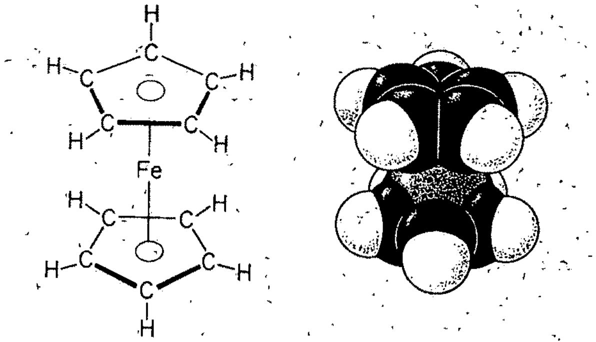

Fig. 1 The structure of ferrocene.

In the chemical literature, references to organometallics first appeared in the early nineteenth century. In 1827 the Danish chemist Zeise[6,7] found that boiling platinum chloride with ethanol and adding potassium chloride produced a substance of composition $KCl{\cdot}PtCl_2{\cdot}C_2H_4{\cdot}H_2O$. More than 100 years were to pass before it was realized that Zeise's salt should be formulated as a coordination compound of platinum, that is $K[C_2H_4PtCl_3].H_2O$, with carbon–metal bonding. Early historical landmarks were Bunsen's synthesis[8] of cacodyl $(CH_3)_2AsAs(CH_3)_2$ in 1842, Frankland's synthesis[9] of alkylzinc compounds in 1849, Mond's synthesis[10] of nickel carbonyl $Ni(CO)_4$ in 1890, and Grignard's discovery[11] of organomagnesium compounds (for example, C_2H_5MgBr) in 1900.

No account of recent developments in organometallic chemistry would be complete without a brief summary of current views on such matters as stability, bonding and structure. Indeed, it is in these areas that some of the most significant recent advances have been made. Studies in this field, as in organic chemistry, have been greatly aided by the application to structural problems of such techniques as nuclear-magnetic resonance spectroscopy and single crystal X-ray crystallography. The discovery of many novel compounds with unusual bonding of organic groups to metals has done much to stimulate preparative work in this field. The application of valence theory, particularly consideration of molecular rather than atomic orbitals, has led to a better understanding of the reactivity of compounds with important consequences for further chemical syntheses.

Stability, Bonding and Structure

All organometallic compounds are thermodynamically unstable to oxidation, the driving force for which is the large favourable free energy change in the conversion into metal oxide, carbon dioxide and water. In this respect organometallic compounds are no different from purely organic compounds except that an additional product (metal oxide) is involved. As in organic chemistry, however, kinetic factors are often decisive in inhibiting oxidation in ambient conditions. Instability to air can often be associated with the presence of empty low lying metal orbitals which can interact with molecular oxygen thereby providing a pathway to decomposition involving little activation energy. Similar considerations apply to hydrolytic instability. Hydrolysis often proceeds by initial bonding of a water molecule, a process facilitated by an empty metal orbital which can accept an electron pair from the substrate. Thus the simpler organo-derivatives of lithium, beryllium or aluminium are readily, sometimes even explosively, decomposed by water or oxygen. The high reactivity can be traced to the ability of these metals first to coordinate a reactant molecule; this is followed by interaction of the bonded substrate with a polar carbon–metal bond. Indeed, whether or not decomposition follows attachment of a substrate molecule depends on the nature of the carbon–metal bond as determined by electronic and steric factors. With electropositive metals such as aluminium the bond may be sufficiently polar in the sense $\overset{\delta+}{M}\text{—}\overset{\delta-}{R}$ that the organic group becomes susceptible to electrophilic attack (for example, from a proton of coordinated water to release RH). Most organometallic compounds are, however, highly covalent in nature because the electronegativity differences between the organic groups and the metal atoms are small. Indeed, the least electropositive metals, such as lead or mercury, form organo-derivatives (for example $(C_2H_5)_4Pb$ or $(CH_3)_2Hg$) which provide excellent examples of covalent compounds with classical two electron, two centre σ bonds. In accord with this they are volatile, hydrocarbon soluble and immiscible with water. By contrast with the behaviour of the light metals mentioned above, chromium forms a cationic benzyl complex $[C_6H_5CH_2Cr(H_2O)_5]^{2+}$ sufficiently stable to have a half-life of about 1.5 day in solution[12]. Even though water molecules are present in the coordination sphere of the metal in the cation, the C–Cr σ bond is insufficiently polar to release the benzyl group as toluene. Addition of acid does, however, decompose the complex.

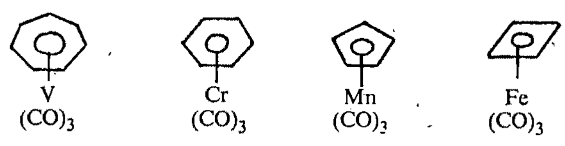
Carbon–mercury bonds form readily from mercury salts in a variety of reactions. These bonds once formed are relatively stable in ambient conditions because the R–Hg group has little affinity for oxygen or water. Organo-mercurials are very poisonous, and the chemical robustness of CH_3Hg and related groups can have serious consequences if they become accumulated in natural food chains through careless discharge of industrial waste. One process for converting acetylene into acetaldehyde depends on a mercury catalyst and effluent from a factory using this process was responsible for several deaths from the so-called Minamata Bay disease. Shellfish removed from the sea for human consumption were subsequently found to contain the compound CH_3HgSMe (ref. 13). The death of birds in Sweden was traced to the use of phenylmercury compounds in the pulp and paper industry; degradation produced elemental mercury which was converted to methylmercury by bacterial action—after ingestion into fish the mercury became concentrated in sea birds. Organomercury compounds have been used in fungicides used in the treatment of wheat and in this manner mercury has been transmitted to humans by way of hogs in New Mexico[14].

The thermal stability of organometallic compounds varies considerably. Some such as the tetraalkyl derivatives of tin or ferrocene are very stable. The last of these survives heating to over 400° C in the absence of air. The robustness of a particular organometallic can be related to the energy required to bring about loss of the organic group as a molecule or a radical and this in turn depends on the activation energy needed to promote a bonding electron from the highest filled molecular orbital of the compound into an anti-bonding orbital. In this way a molecule C_nH_n could dissociate from π-C_nH_nM, and a radical R, which could irreversibly dimerise to R_2, might form from σ-RM (where M is a metal atom with attendant ligands). In the last case an alternative mode of decomposition involves release of olefin through the reaction $\sigma\text{-}CH_3CH_2M \rightarrow C_2H_4 + HM$. The reverse of this reaction is important in the synthesis of organometallic compounds.

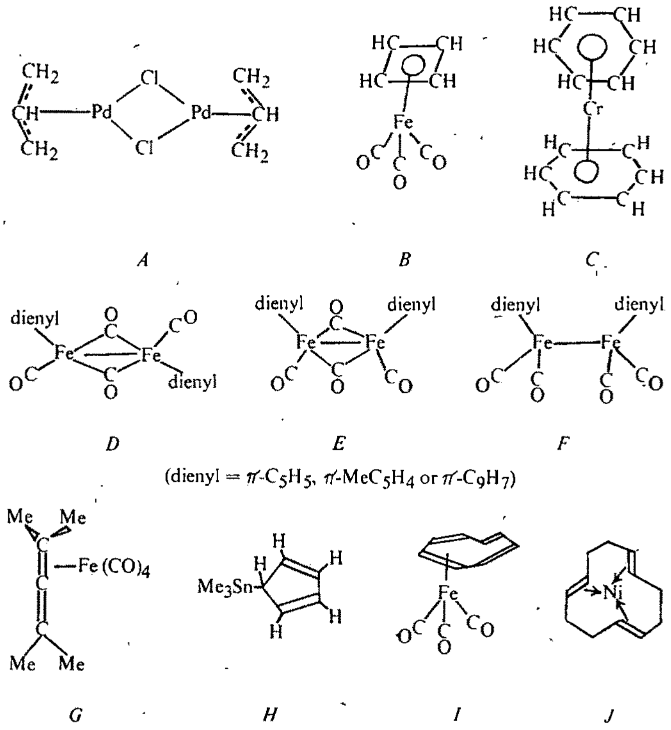
Evidently the energy required for decomposition is very small for a molecule such as $(CH_3)_4Ti$ which decomposes above −78° C, whereas it is high for a molecule such as ferrocene or $(Ph_3P)_2Pt(CH_3)_2$. Phosphines are especially effective ligands for stabilizing carbon–metal σ bonds and it has been suggested that they modify the relative energies of the orbitals so that the energy difference between the highest occupied and lowest unoccupied orbital is increased[15,16]. The stability of ferrocene may be correlated with the complete electron occupation of all bonding orbitals (the iron atom acquires a pseudo-krypton electron configuration according to the "effective atomic number rule") coupled with the relatively high energy of the anti-bonding orbitals, the transfer of electrons to which would destabilize the compound.

π-Complexes

Ferrocene[17,18] is but one of many so-called "π-complexes", most of which have been prepared in the past ten or fifteen years. π-Complexes are coordination compounds in which unsaturated organic systems are associated with metals, which may or may not have other ligands present. Examples include Zeise's salt (mentioned earlier), allylpalladium chloride[19–21], cyclobutadieneiron tricarbonyl[22] and *bis*(benzene)-chromium[23] (Fig. 2*A*, *B* and *C*). Generally the bonding of these unsaturated groups to the metals is interpreted in terms of donation of π electrons from the hydrocarbon into vacant d orbitals of the metal, coupled with transfer of electrons from the metal to the ligand by way of overlap of filled orbitals of the metal with empty anti-bonding (π^*) orbitals of the hydrocarbon. The components of the bond thus involve opposing electron flows and as such tend to strengthen one another (a synergic effect). This concept stems from consideration of the nature of the bonding of the ethylene to platinum in the anion of Zeise's salt $[(\pi\text{-}C_2H_4)PtCl_3]^-$ (refs. 24, 25). The overall effect on the stereochemistry of the complexes is that all the carbon atoms of the unsaturated systems are equivalently bonded to the metal atoms, for example



It follows that if retrodative bonding is important for the existence of the compounds, metals will generally only form π-complexes when they are in low oxidation states because only then will filled d orbitals be available on the metal atoms to partake in bonding with π^* orbitals of the hydrocarbon groups. In support of this concept, it has been found experimentally that the new organic chemistry of the transition elements is most extensive when the metal is in a relatively low oxidation or valence state. Moreover, the discovery of countless π complexes has brought about a convergence of organometallic and coordination chemistry. Thus nickel is formally zerovalent not only in the well recognizable coordination complexes $K_4[Ni(CN)_4]$ and $Ni(PF_3)_4$ but also in the π-complex $Ni(\pi\text{-}C_8H_{12})_2$ (C_8H_{12} is cycloocta-1,5-diene).



(dienyl = π-C_5H_5, π-MeC_5H_4 or π-C_9H_7)

Structural Studies

Although infrared and nuclear magnetic resonance (NMR) spectroscopy are used extensively in the study of organometallic compounds, the increasing complexity of the complexes discovered makes the X-ray crystallographic method the final arbiter of structures. This analytical technique has been greatly facilitated by computer processing of data, and about 150 new organometallic structures are now determined by this technique each year. Important though the X-ray study of single crystals is, however, it has become increasingly clear in the past decade that the structure of an organometallic in the solid state is not necessarily the same as that operating in solution. This is because many of the molecules are stereochemically non-rigid. The intramolecular rearrangements can take two forms; the first involves tautomerism wherein non-equivalent structures are detectable, often by infrared spectroscopy. Thus the cyclopentadienyliron carbonyl complex $[Fe(CO)_2(\pi\text{-}C_5H_5)]_2$ has the centro-symmetric structure (Fig. 2*D*) in the crystal with two bridging and two terminal CO ligands[26]. The infrared spectra of this and related complexes (dienyl = π-MeC_5H_4 or π-C_9H_7(indenyl)) in solution are, however, solvent dependent, and vary in a manner that indicates an equilibrium between the forms indicated in Fig. 2*D*, *E* and *F*; the last form is present only in small amounts[27]. A second phenomenon, even more widely observed, involves interconversions between equivalent structures which are therefore of equal free energy content. Such molecules are termed fluxional[28]; atoms of a given element exchange sites within the molecule at a speed which can be detected by n.m.r. spectroscopy. This spectroscopic technique operates on a time scale 10^{-1} to 10^{-9} s, similar to that of the dynamic processes whereby molecules pass from one configuration to another involving a different permutation of the nuclei.

Several types of fluxional organometallic molecules are known. An interesting example in the acyclic olefin category is the tetramethylallene complex[29] (Fig. 2*G*). The instantaneous structure shown should give rise to a proton NMR spectrum with three sets of resonances (relative intensity 1 : 1 : 2), whereas a single sharp signal is observed at 25° C. It is reasonable to assume that the $Fe(CO)_4$ group moves from end to end of the allene group at a speed greater than the time scale of the NMR experiment. Such intramolecular processes should slow down when the temperature is lowered and in accord with this at −60° C the spectrum of the structure shown in Fig. 2*G* appears as the expected three signals.

Many non-transition metal and transition metal compounds containing σ-bonded cyclopolyene groups show fluxional behaviour. For example, the chemical behaviour of the cyclopentadienyl compound $Me_3Sn(\sigma\text{-}C_5H_5)$ (Fig. 2*H*) suggests the 1,3-diene system shown, which would imply three different environments for the protons. The spectrum nevertheless shows only a single peak indicating a rapid movement of the carbon–metal bond among the five possible positions.

Among the most intensively studied fluxional organometallics are those involving coordination of a cyclic polyolefin to a metal carbonyl group, the cyclic olefin having more π-electrons than the metal needs to achieve the effective atomic number rule (that is, 4 for the $Fe(CO)_3$ group and 6 for the $Mo(CO)_3$ group). A classic example of this behaviour is the cyclooctatetraene complex (Fig. 2*I*). The structure shown has been established in the crystal state by X-ray methods[30]. The diffraction of X-rays takes place on a time scale of 10^{-18} s and so this technique "sees" the instantaneous structure. At room temperature the proton NMR spectrum of $(\pi\text{-}C_8H_8)Fe(CO)_3$ shows a single peaking indicating that all protons are equivalent which is not in accord with a rigid structure as shown in Fig. 2*I*. Apparently the locus of the metal attachment to the four carbon atoms of the ring shifts at such a speed that the protons appear to be equivalent. On lowering the temperature to −150° C the spectrum becomes more complex; for example, that of the ruthenium analogue $(\pi\text{-}C_8H_8)Ru(CO)_3$ displays four bands as the intramolecular rearrangement slows down[31,32]. The mechanism by which this occurs—for example, a 1,2-shift of the $M(CO)_3$ group around the ring, is not known with certainty partly because of the experimental difficulties of knowing whether the limiting spectrum corresponding to rigidity has been reached even at ~ −150° C (ref. 33).

Chemical Reactivity

The rapid expansion of organometallic chemistry in recent years has had many important consequences which have stimulated research. It has become clear that there are numerous ways in which organic groups can be combined with metals and because metals vary so much in their chemistry, quite different properties are found for organometallic compounds involving the same organic group but different metallic elements. The extraordinary development of the organic chemistry of the transition metals has followed in part from the recognition that the properties of organometal groups are influenced by the presence of other ligands in the coordination sphere of the metal. In other words, because of their electronic and steric effects, particular ligands can act as fine tuners in determining the reactivity of others.

In dealing with such wide variations of chemical behaviour in the context of developments in recent years it is convenient to separate the organo-derivatives of the main group metals from those of the transition metals. Such a separation is, however, somewhat arbitrary because many compounds are known containing both main and sub-group metals associated with organic moieties.

Main Group Metals

During the first half of this century it became widely recognized that organolithium and organomagnesium compounds were valuable in synthesis. In 1956 it was discovered that diborane (B_2H_6), generated *in situ* from sodium borohydride and a boron halide, added rapidly to olefins in the presence of ether (for example, diglyme $(CH_3OCH_2CH_2)_2O$) (refs. 5, 34, 35).

$$12RCH:CH_2 + 3NaBH_4 + 4Et_2O.BF_3 \xrightarrow{\text{diglyme}} 4(RCH_2CH_2)_3B + 3NaBF_4 + 4Et_2O$$

It has been found possible to cleave the C–B bonds thus formed in a variety of ways, and this reaction, termed hydroboration, has become the basis of many organic syntheses comparable in importance with the earlier discovered Grignard and lithium reagents. Thus treatment of a triorganoborane with alkaline hydrogen peroxide yields an alcohol RCH_2CH_2OH, whereas protonation by acid gives RCH_2CH_3, that is, an overall hydrogenation of a double bond. Oxidation of $(RCH_2CH_2)_3B$ with chromic acid gives ketones or acids, whereas treatment with bromine and sodium methoxide gives RCH_2CH_2Br (an overall anti-Markownikov addition of HBr to $RCH:CH_2$). Many related organic syntheses depend on the hydroboration of acetylenes or dienes as the first step, and with olefins, acetylenes or dienes the substituents on the double or triple bonds can be complex organic groups so that the reaction has very wide scope throughout organic chemistry.

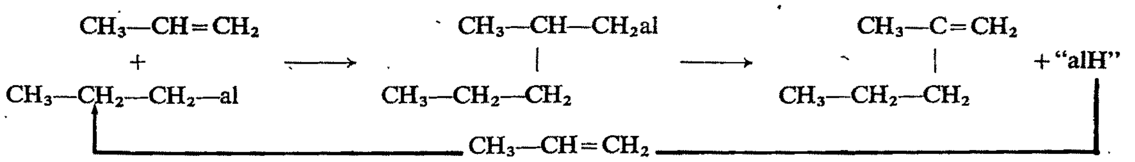
Hydroboration is formally related to the so-called "direct syntheses" of aluminium alkyls developed by Ziegler and his coworkers[4]:

$$Al + 3H_2 + 3(1\text{-olefin}) \rightarrow alkyl_3Al.$$

Moreover, aluminium alkyls themselves react with olefins in a stepwise growth reaction:

$$R_3Al + 3nC_2H_4 \rightarrow [R(CH_2CH_2)_n]_3Al.$$

As aluminium alkyls are readily oxidized to alcoholates $(RO)_3Al$ which in turn can be hydrolysed, this process forms the basis for a conversion of ethylene into long chain primary alcohols. The importance of the aluminium alkyls does not, however, end with the synthesis of alcohols needed for the detergent industry. Propylene when heated with tripropylaluminium under pressure is converted into 2-methyl-1-pentene



$((C_3H_7)_2AlH = alH)$

Rearrangement of 2-methyl-1-pentene into 2-methyl-2-pentene followed by elimination of methane by cracking affords the important monomer isoprene (synthetic rubber).

Transition Metals

Spurred by the recognition of the sandwich structure of ferrocene and the discovery within the following decade of such compounds as dibenzene chromium (Fig. 2*c*, ref. 23) and cyclododeca-1,5,9-trienenickel (Fig. 2*J*, refs. 36, 37), new organo-complexes of the transition metals were characterized very rapidly[38]. This period of research activity was accompanied by a growing awareness of the many ramifications of this field. Among the more important of these may be mentioned the following.

(i) It is relatively easy to prepare metal complexes containing hydrocarbon groups if certain other ligands are also present, particularly carbon monoxide and phosphine groups. Moreover, it is also possible to prepare complexes containing only hydrocarbon ligands if either the metal is preconditioned by a reductive process in the presence of a hydrocarbon which then uses its π electrons to fill the metal's bonding orbitals, or a salt is treated with a suitable carbanion so that in the organometallic produced the metal remains in the same stable valence state. Such syntheses are illustrated by the preparation of the nickel complex $Ni(\pi\text{-}C_8H_{12})_2$ by reducing nickel acetylacetonate with aluminium alkyls in the presence of cycloocta-1,5-diene (ref. 39), and the preparation of *bis*-(π-allyl)nickel by the reaction[40]

$$2C_3H_5MgBr + NiCl_2 \xrightarrow[-10^\circ C]{\text{ether}} Ni(\pi\text{-}C_3H_5)_2 + 2MgBrCl \quad [Ni(II)d^8]$$

(ii) The mode of bonding of an organic group to a metal can change from the σ to the π form or vice versa, for example

$$(\sigma\text{-}CH_2 : CHCH_2)Mn(CO)_5 \underset{\text{pressure}}{\overset{\text{u.v.}}{\rightleftarrows}} (\pi\text{-}C_3H_5)Mn(CO)_4 + CO$$

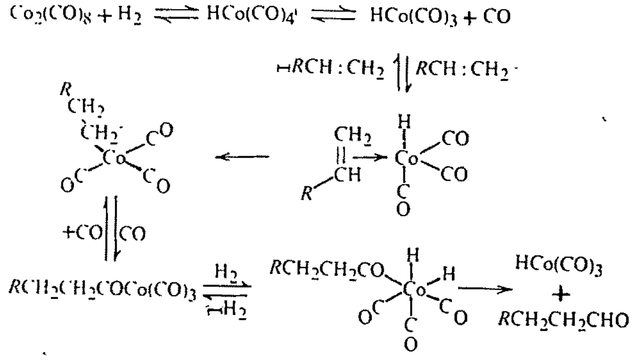
$$(\sigma\text{-}CH_2 : CHCH_2)Fe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{H^+} [(\pi\text{-}CH_3CH : CH_2)\ Fe(CO)_2(\pi\text{-}C_5H_5)]^+ \underset{Ph_3C^+BF_4^-}{\overset{NaBH_4}{\rightleftarrows}} (\sigma\text{-}(CH_3)_2CH)Fe(CO)_2(\pi\text{-}C_5H_5)$$

Such transformations are the key to certain catalytic reactions of technological importance to be described later. Moreover, these rearrangements fall into the category of reactions of coordinated ligands, an area of coordination chemistry which has been developed significantly in recent times[41].

(iii) It has been amply demonstrated that reactions can be carried out on organic groups coordinated to transition metals, and indeed the metal can either donate or withdraw electron density from an organic moiety so that its substituent effect is profound. Metals are also multisite substituents with the sites disposed in accord with the metal's coordination characteristics. There has been a growing appreciation of the chemical consequences of the control of organic reactions by metals in the past decade, so that the mechanisms of a number of processes catalysed by transition metals are better understood; and some principles have been developed which have made the search for new catalysts less empirical.

Even before the discovery of ferrocene and related π-complexes, it was known that some organic syntheses were catalysed by transition metal complexes. Roelen[42] studied the mechanism of the Fischer–Tropsch synthesis and discovered the oxo or hydroformylation reaction which generates aldehydes and alcohols from olefins, carbon monoxide, and hydrogen in the presence of cobalt catalysts. Reppe *et al.*[43] discovered that acetylene in the presence of nickel compounds can be cyclized to cyclooctatetraene and almost concurrently with the isolation of ferrocene, Ziegler *et al.*[4,44] found that the addition of transition metal halides to triethylaluminium produced a catalyst capable of polymerizing ethylene or propylene under mild conditions; this polymerization occurs in a sterically regular way[45]. It has come to be recognized recently that all these processes have in common one of the most basic of all ligand reactions, namely the combination of two ligands within the coordination sphere of the metal in a so-called "insertion" step. This is well illustrated by the presently favoured mechanism for hydroformylation[46] shown in the scheme below. The catalyst is believed to be the hydridocarbonyl $HCo(CO)_3$ which can bond an olefin molecule to form a π-complex because the cobalt atom is only four-coordinate ("coordinatively unsaturated"). Addition of the Co–H bond to the olefinic double bond affords an alkylcobalt tricarbonyl in an insertion step which involves rearrangement of a π into a σ-complex. The σ-complex is again coordinatively unsaturated, and reacts with CO to give an acylcobalt tricarbonyl in another insertion reaction. From mechanistic studies this is more properly regarded as a migration step in which an attacking CO ligand bonds to a vacant site on the cobalt atom thereby promoting transfer of the RCH_2CH_2 group onto one of the terminal CO ligands. The acylcobalt tricarbonyl complex involves $Co^I(d^8)$ and as such is able to cleave hydrogen molecules to form, by so-called oxidative addition, a cobalt (III) (d^6) complex in which the components necessary to produce the aldehyde and regenerate the catalyst are brought together in close proximity in the metal's coordination sphere.

The generality of the insertion process is evident from the fact that it may be used to explain the function of the Ziegler–Natta catalysts. Stereospecific coordination of an olefin molecule to a vacant site on a titanium atom adjacent to a σ-bonded growing polymer chain can continue indefinitely for as long as the coordination step is followed by an insertion.



Catalysis

Studies on hydroformylation, hydrogenation and isomerization of olefins, and the oligomerization of dienes and acetylenes by transition metal complexes have, in the past, been predominently empirical in nature in that one of a wide range of complexes tested has been found capable of promoting a certain type of reaction. As yet we are far from being able to design catalysts for a given purpose because knowledge of the kinetic and thermodynamic factors which lead to formation of a complex and its subsequent breakdown in a desired way is too imprecise. Recent work has, however, amply demonstrated the importance of vacant coordination sites, σ–π transformations of organic groups, the widespread occurrence of insertion reactions—in particular those involving metal–hydrogen and metal–alkyl bonds—and the fact that there are a large group of syntheses which depend on the ability of transition metals to pass readily from one oxidation state to another. A good example of this ability is provided by the compound $(Ph_3P)_3RhCl$, an effective hydrogenation catalyst which operates because rhodium(I) bonds olefins and can readily be "oxidized" by molecular hydrogen to a rhodium(III) hydrido-species which transfers hydrogen to an olefin molecule so that the catalyst is regenerated[47,48].

Many of the principles now associated with the reactions of organic groups bonded to transition metals are also applicable to biological processes where "metal-containing" enzymes catalyse isomerization and transmethylation reactions. As yet there is little evidence that metal–carbon bonds play any extensive role in biological chemistry though vitamin B_{12} forms C–Co bonds in its conversion to coenzymes (ref. 49 and references therein). In biological processes involving metals, the important ligand atoms are nitrogen and oxygen, but as both areas are part of the broader field of coordination chemistry as such, the study of one is likely to have some relevance to the other. And in the context of reactions of coordinated ligands, irrespective of whether metal–carbon, metal–nitrogen, or metal–oxygen bonds are involved, recent studies have shown that metal ions can assist either nucleophilic or electrophilic attack on a ligand depending whether the metal is in an electron-withdrawing or an electron-donating environment. These characteristics depend on the metal involved, its oxidation state, and also on the nature of all the ligands, and almost infinite variations in reactivity seem possible.

Olefins are not normally subject to nucleophilic attack. By contrast, coordination of, for example, ethylene to Pd^{+2} makes possible a reaction with water to yield acetaldehyde. This is the basis of the technologically important Wacker process[50,51]. The overall reaction ($C_2H_4+\frac{1}{2}O_2\rightarrow CH_3CHO$) results from a combination of several steps. Thus in one variation of this basic reaction, ethylene and oxygen are passed through an aqueous solution of palladium and cupric salt.

$$C_2H_4+PdCl_2+H_2O\rightarrow CH_3CHO+Pd^\circ+2HCl \quad \text{(product forming reaction)}$$

$$Pd^\circ+2CuCl_2\rightarrow PdCl_2+2CuCl \quad \text{(Pd oxidation)}$$

$$\underline{2CuCl+2HCl+\tfrac{1}{2}O_2\rightarrow 2CuCl_2+H_2O} \quad \text{(CuCl oxidation)}$$

$$C_2H_4+\tfrac{1}{2}O_2\rightarrow CH_3CHO$$

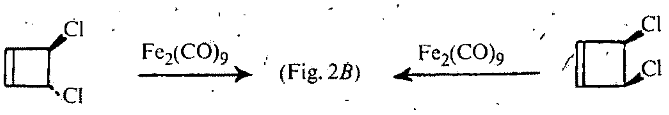
In the first reaction it is assumed that $[(\pi\text{-}C_2H_4)PdCl_3]^-$, closely related to the anion of Zeise's salt, is an intermediate. Ligand exchange of H_2O for Cl^- then gives $[(\pi\text{-}C_2H_4)Pd(H_2O)Cl_2]$ which releases a proton (H_3O^+) and affords $[(\pi\text{-}C_2H_4)PdCl_2(OH)]^-$. In the last of these species ethylene donates π-electrons to an electron accepting palladium (oxidation state +2) thereby promoting nucleophilic attack of OH^- (already within the metal's coordination sphere) on one of the carbon atoms to give a σ-bonded organo-palladium intermediate $[\sigma\text{-}CH_2\text{-}OHCH_2PdCl_2]^-$. The nominally vacant coordination site (it may be solvent occupied) on palladium would subsequently promote transfer of a β hydrogen atom, by way of transient Pd-H, to give an unstable carbonium ion $CH_3\overset{+}{C}(H)(OH)$ which affords acetaldehyde and a proton (hence HCl). Palladium metal is also formed and is reoxidized by cupric chloride. Addition of acetic acid as a reactant leads to the formation of vinyl acetate by attack of OAc^- on coordinated ethylene. Vinyl acetate is important as a monomer for lattices in paints, fibres and resins. Unfortunately there are important corrosion problems in its production by the liquid-phase palladium chloride process.

In other reactions π-complexes are susceptible to electrophilic rather than nucleophilic attack. In these cases the metal is in a low oxidation state so that electron density is available for transfer to the π^* orbitals of the ligand which thus becomes susceptible to Friedel–Crafts type substitutions, protonation or loss of hydride. The latter process, first reported in 1958 (ref. 52) has been used extensively in organometallic syntheses. For example, cycloheptatrienemolybdenum tricarbonyl reacts with trityl borofluoride $Ph_3C^+BF_4^-$ to give Ph_3CH and the cationic complex $[(\pi\text{-}C_7H_7)Mo(CO)_3]^+$. Interestingly, in the cation the effect of the metal, now in a more positive oxidation state, is to make the C_7H_7 group susceptible to attack by nucleophiles (for example, $R^-=CN^-$, OMe^-, Ph^- and so on) thereby producing cycloheptatriene derivatives $(\pi\text{-}RC_7H_7)Mo(CO)_3$ (ref. 53).

Many olefin–metal complexes can be protonated[38] so that a hydrogen atom becomes attached to the hydrocarbon group. As well as rendering an olefin susceptible to protonation it is probable that the metal plays a rather direct role, through metal–hydrogen bond formation, in transferring the proton to the ring[54,55]. Much research needs to be done to establish mechanistic details of metal-assisted electrophilic reactions in general, but it is clear that reactions of this kind have considerable potential in organic syntheses. Thus cyclooctatetraene does not undergo electrophilic reactions to give substituted derivatives. This is not true for cyclooctatetraene-iron tricarbonyl which undergoes both addition and substitution reactions with electrophiles (for example, $POCl_3$ in dimethylformamide, or CH_3COCl and $AlCl_3$) to give cyclooctatetraene derivatives coordinated to an $Fe(CO)_3$ group[56]. Treatment of the products with ceric salts liberates the substituted cyclooctatetraene. Pettit and his coworkers[57] first used this method for removing coordinated olefins from metals, and subsequently applied the technique in elegant studies on cyclobutadiene and its derivatives[58,59].

Cyclobutadiene Chemistry

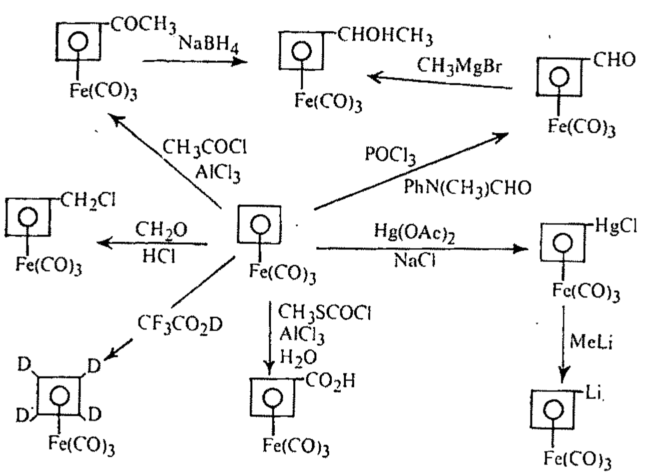
Mention was made earlier of the advances in organometallic chemistry which have led to the isolation of normally unstable organic moieties by coordination to a transition metal. The practical and theoretical problems associated with the cyclobutadiene molecule have concerned organic chemists for a hundred years. In perhaps the only example in organometallic chemistry where theory has been used to predict an experimental result, instead of accounting for it after it has been observed, Longuet-Higgins and Orgel[60] suggested that in spite of the instability of cyclobutadiene itself it would act as a good ligand. This suggestion was confirmed by the isolation of a stable tricarbonyliron complex of tetraphenylbutadiene by a serendipitous method[61] (many of the best discoveries in the field have been made by chance), and by the characterization of a dimeric form (bridging chloride ligands) of tetramethylcyclobutadiene-nickel (ref. 62). The parent ligand was prepared by the synthesis[58,59]



Cyclobutadieneiron tricarbonyl is an aromatic system in that it readily undergoes electrophilic substitution reactions. Moreover, the substituents introduced in this way undergo functional group chemistry without destabilization of the iron–cyclobutadiene bond (see structure 4).

The oxidative decomposition of cyclobutadieneiron tricarbonyl with Ce^{4+} has revealed several novel compounds through Diels–Alder type reactions, as indicated in Fig. 3.

The product from phenylacetylene is a molecule in which one ring has the Dewar benzene structure whereas the other has the Kekulé structure. Although this is somewhat of a laboratory curiosity, cyclobutadiene–iron tricarbonyl chemistry



Structure 4.

does have considerable potential in organic syntheses. Thus in recent years there has been much interest in cubane chemistry, and this synthesis of a dicarboxylic acid derivative is relatively simple. The ring system has previously been accessible only by elaborate reaction sequences.

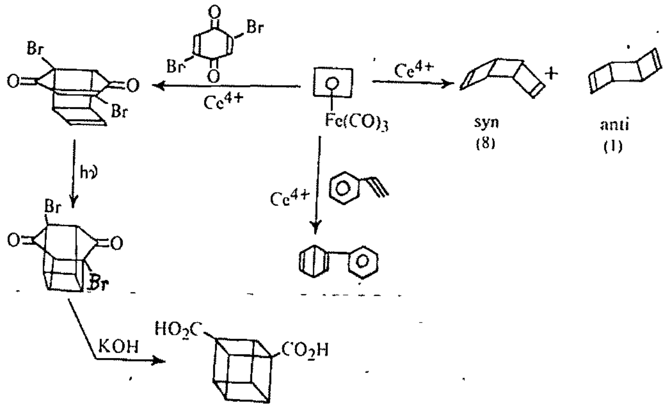


Fig. 3 Compounds revealed by the oxidative decomposition of cyclobutadieneiron tricarbonyl.

Predicting the Future

Although only a few organometallic compounds are widely used for specific purposes (for example, silicone polymers, tetraalkyl leads), their value in synthesis either as intermediates or as catalysts is great, and likely to increase in the future; and as organometallic chemistry impinges on both inorganic and organic chemistry research in this area helps to unify chemistry. But many problems remain to be solved. Previously insufficient attention has been given to a mechanistic approach in the study of organometallic reactions. Our knowledge of the bonding in organometallic compounds, particularly those involving transition elements, remains at best imprecise. Although some significant advances have been made in the design of homogeneous catalysts often little is known about the exact composition of the catalysts under the working conditions. Studies of a synthetic and structural nature of polynuclear metal complexes containing hydrogen and organic groups as ligands may eventually allow a better understanding of heterogeneous reactions, particularly the reactions of hydrocarbons on metal and metal oxide surfaces. It is difficult to predict the future of this field but it certainly has more momentum than many areas of chemistry.

Lightning Observations by Satellite

J. G. SPARROW & E. P. NEY

School of Physics and Astronomy, University of Minnesota, Minneapolis, Minnesota 55455

The data from OSO-5 confirm the OSO-2 result that storm complexes at night are chiefly found over land. The North Atlantic Ocean seems to have more lightning storms associated with it than other regions of ocean whereas the principal desert regions display a marked scarcity.

OBSERVATIONS of the positions of night-time lightning storms during the new Moon periods from February to October 1965 have already been reported[1] from the satellite OSO-2. A similar instrument was also flown on OSO-5, launched in January 1969, and this article reports the new data.

The Minnesota experiment[4] on OSO-5 consisted of six photometers, four of which can be used to detect lightning strokes. This analysis is based on data from two of these, each having a 10° angular diameter field of view looking along the spin axis of the satellite in the direction opposite to that of the solar sail. Each photometer is sensitive to a broad spectral region, astronomical blue (approximately 3500 to 5000 Å) and red (approximately 6000 to 8000 Å) respectively. The photometers are sampled three and two times per 0.32 s when the satellite is in darkness. The time constants of the two telescopes are each approximately 0.1 s. The photometers are protected from excessive light levels by protective photodiodes which disconnect the high voltage supply at times when the light level is above a minimum value. This effectively limits the observational periods to times near new Moon.

Storm Complexes

The data were searched by the computer (CDC 6600) to separate abrupt increases that might be interpreted as lightning. Manual examination further refined the selection, taking into account the expected time constant of the signal decay, and the positions of lightning storm complexes were plotted. These were taken to be areas (several square degrees) containing one or more active lightning cells which gave rise to two or more lightning flashes visible at the satellite. This criterion (to reject a single flash seen by two telescopes) became necessary to remove some abrupt increases in the apparent light level that cannot be interpreted as lightning. The distribution of the lightning storm complexes (Fig. 1) is similar to that found previously, confirming the result from OSO-2 that the distribution of night-time storms is heavily biased towards land areas rather than similar areas of sea. As the satellite coverage is relatively uniform in bands of constant latitude, Fig. 1 may be interpreted directly as an indication of non-uniformity. About 1,000 storm complexes have been plotted in Fig. 1 from the data on some 7,000 lightning strokes. As the results from the new Moon period February to September 1969 (20 to 24 h local time) were similar to those from January to July 1970 (00 to 04 hLT), the data have been combined in one plot.

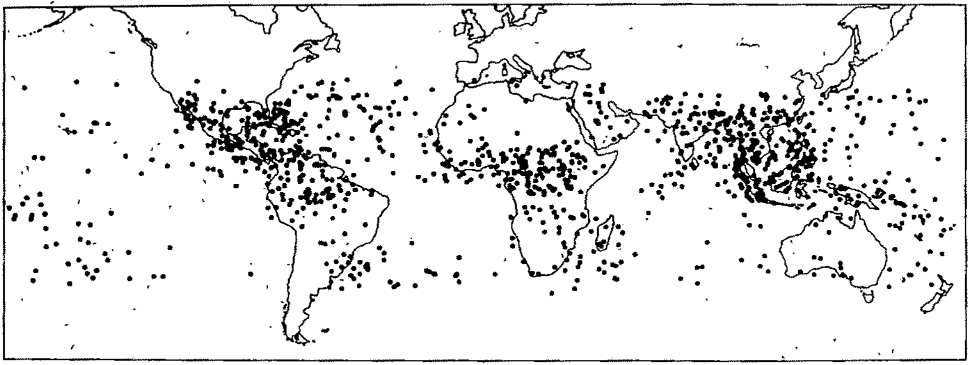

Fig. 1 Distribution of night-time lightning storm complexes observed by photometers on board satellite OSO-5.

It is evident that these data are in agreement with Schonland's statement[2] that "thunderstorms are not very frequent over the oceans; exceptions are the areas off the south-east coasts of Brazil and South Africa, and the seas surrounding the islands of the East Indies and Madagascar". It is also apparent that the North Atlantic Ocean has more lightning storms than similar areas of other oceans. There is a marked scarcity of lightning storms in the principal desert regions (Sahara and Kalihari Deserts, Great Australian Desert and the area in central South America) even compared with those over the North Atlantic Ocean.

The field of view of the photometers on the Earth ranges from approximately one square degree when the photometers view vertically to a maximum value of approximately 12 square degrees just before the field of view leaves the Earth. From the total time scan (~200 h) and the area-time scan (~400 degree^2 h) the mean area of the field of view is found to be approximately 2 square degrees. The number of lightning strokes in each storm complex varied from a minimum value of two to about thirty strokes seen in 2 min; most of the last group were observed simultaneously by both telescopes.

Spurious Events

On some occasions apparent "lightning strokes" were detected that could not be assigned as such because at the time the fields of view of the telescopes were well above the Earth. Some of these were detected by as many as three photometers simultaneously when the photometers were looking above the satellite. The decay time indicates that the signal probably originated forward of or in the photomultiplier preamplifier systems. Because the electronics associated with each photomultiplier are isolated from each other (although sharing the primary spacecraft power) it is unlikely that these apparent increases are electronic in nature. Furthermore, if the increases were initiated by feedback through the spacecraft batteries then all six photometers would probably show similar effects. This has occurred at other times when noise is present in the data but in these cases the characteristic time constant is not seen in each photometer signal. On the occasions under discussion, only those photometers viewing in the anti-sail direction and not those viewing in the opposite direction have been affected. The possibility of spurious reflexions from the front light baffles of each photometer (for example, from lightning, meteors and so on) can probably be eliminated because of the large attenuation in the scattered signal compared with the direct signal when the photometers view close to the Moon. The distribution of these signals over the Earth's surface is approximately random, suggesting that the source is not lightning. Single occurrences are seen about once every ten orbits. No acceptable mechanism has yet been found to explain these anomalous data spikes.

These increases, which seem to be due to short duration (<0.1 s) "light" flashes, arise from processes other than lightning and must be eliminated from the data before any discussion of lightning distribution can be entered into. This has effectively been done by accepting as storms only those occasions when two or more strokes were observed. In this way some seventy occasions when one stroke only was seen simultaneously by the two telescopes—when their fields of view were on the Earth—have been eliminated.

No Change in Frequency

The earlier experiment on OSO-2 was conducted during solar minimum conditions (1965) whereas these later measurements were made at a more active solar period. If a substantial change in the worldwide frequency of night-time lightning storms occurred between these two periods it should be detectable from a comparison of the frequencies observed by the two satellites. That such a relation might exist between solar activity and increased storminess has been suggested by Ney[3]. Taking into account the increased sensitivity in the later experiment it does not seem that any significant change was detected (the accuracy of the comparison is not better than perhaps a factor of two). A search for solar activity effects can also be made by looking for a correlation between lightning storm occurrence and K_p or another magnetic index within the data from one of these experiments. No significant correlation was found for lag/lead times of as much as 24 h between the time of storm occurrence and the three hourly value of K_p in the data of this experiment or in the less statistical data of OSO-2. These findings are not unexpected, for Markson[4] has shown, from data supplied by Lethbridge, that there is no apparent correlation between annual thunderstorm activity in the US and the solar cycle. Brooks[5] and Likhter *et al.* (quoted by Markson[4]) have also shown that there is low correlation between these parameters for low latitude stations.

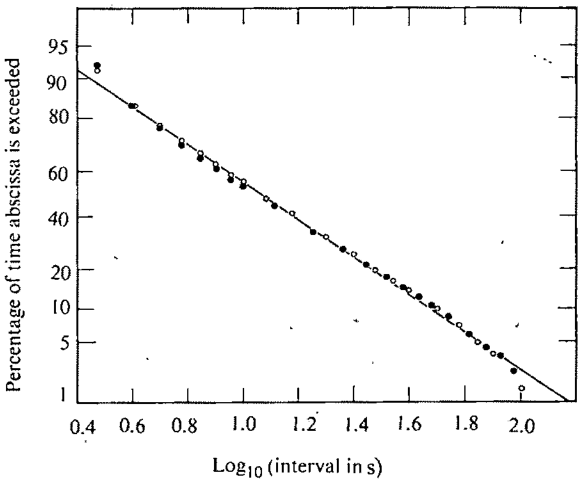

Fig. 2 Time intervals between successive lightning flashes plotted separately for the periods February to September 1969 and January to July 1970.

To reduce the computer time required for the original selection of likely lightning strokes, the computer was instructed to skip forward ten data points after each stroke was found (for one of the photometers). This restriction (to intervals longer than 2 s) avoided the detection of the rapid variations of intensity within a "single stroke". Individual lightning strokes have typical mean durations of 200 to 500 ms (ref. 6). It has been found that the logarithm of the intervals between lightning flashes (as well as the logarithm of the duration of the flashes) within a given storm, or within any of a number of simultaneously occurring storms, are normally distributed[6,7]. The data reported here correspond to those from one thousand storms distributed over 60° of latitude (at all longitudes) throughout most months of the year (1969 to 1970). It is apparent from Fig. 2—in which the time intervals between individual lightning flashes for the periods February to September 1969 and January to July 1970 are plotted—that these data also follow a lognormal distribution. The intervals for both periods belong to the same lognormal distribution with a median flash interval of 11.5 s and a standard deviation of 0.48 log$_{10}$ units.

This work was supported by NASA and the US Office of Naval Research. A detailed description of the experiment will be published later.

Formation of New Connexions in Adult Rat Brains after Partial Deafferentation

P. D. WALL & M. D. EGGER

MRC Cerebral Functions Research Group, Department of Anatomy, University College, Gower Street, London WC1E 6BT

Mapping of the receptive fields of cells in the thalamus and cortex after section of the dorsal columns in the rat reveals evidence of functional reorganization in the central nervous system.

BRAIN damage in adult mammals may be followed by remarkable recovery or by a depressingly permanent defect. Any understanding of this sometime plasticity would be important not only for therapy but also for understanding how the central nervous system adjusts to its environment during development and learning. During experiments designed for a different purpose, we came across evidence that a group of cells which had been deprived of their major input began to respond to quite novel stimuli after a few days. In these experiments, the cell bodies of the normal major input had been destroyed. The one class of explanation which cannot be invoked is true regeneration in which cells had divided and replaced the destroyed cells. In the mammalian adult central nervous system (CNS) there is no evidence for nerve cells which are still capable of division, growth and differentiation: following destruction of nerve cells, non-neural elements divide and migrate into the region of damage, phagocytosing the wreckage and replacing it with an impenetrable scar. Even if the cell bodies are intact but their axons are severed, there is no evidence of successful regeneration of axons within the CNS.

Our experiments involved the dorsal columns, through which cutaneous sensory afferents travel from the hind limbs to terminate on cells of nucleus gracilis. From this nucleus, axons decussate and project to the ventral posterior nucleus of the thalamus (VPL). Similar projection systems pass from the forelimb by way of the cuneate nucleus and from the face through the trigeminal nucleus. Within this region of the thalamus, the entire contralateral body surface is represented in an exact somatotopic map (Fig. 1). Recent experiments have suggested that discriminative cutaneous sensation survives the destruction of the dorsal columns[1]. One explanation for this lack of effect is that other systems converge onto the thalamic nucleus and transmit the necessary afferent information by alternative pathways. To test this hypothesis, experiments were in progress to examine the response of cells in VPL before and after part of the dorsal column–medial lemniscus system had been destroyed. Responses had been recorded in VPL immediately before and after section of thoracic dorsal columns in eleven rats, and after destruction of one nucleus gracilis in eight rats. We suspected that the full potentiality of the cells might not be revealed immediately after deafferentation and therefore decided to leave the animals for various times after the lesion before examining the thalamus. We encountered the unexpected result that cells in VPL which normally respond to leg stimulation began to respond to arm stimuli some time after destruction of nucleus gracilis. We shall report elsewhere the effect of acute and chronic deafferentation on the response of VPL cells to leg and body stimulation. Here we concentrate on those cells whose receptive fields switched from leg to arm.

Recordings were made in seventy-seven adult rats, ASH–CSE strain, weighing 200–400 g, under urethane (25%) anaesthesia, 0.65 ml./100 g. The head was held in a stereotactic machine with the lambda vertically above the ear bars in which position the centre of VPL is A 4.5, L 3.0 and 5.0 mm below cortical surface. The nucleus is crescent shaped in cross section and extends 1.4 mm rostrocaudally and mediolaterally. Thalamic recordings were made with glass-covered platinum microelectrodes whose impedance was 600–800 kohms at 1,000 Hz. When marking of electrode sites was required, recording was first carried out with silver plated steel microelectrodes followed by electrolytic deposition of iron which was later located by the prussian blue reaction. Cortical unit recordings were made with glass microelectrodes filled with 3 M KCl with impedance of 2–4 M ohms. When latencies were required, electrical stimuli were applied to the cutaneous receptive field of the unit through intradermal 30 gauge needles. Chronic lesions of nucleus gracilis or dorsal columns were made in sterile conditions with the animal anaesthetized with 'Equithesin'. With the head fully flexed and the cisterna magna open, nucleus gracilis can be observed directly without further dissection. The nucleus was destroyed by repeated maceration with honed jeweller's forceps. At various times after this lesion, thalamus or cortex was mapped and then the extent of the lesion was determined from serial frozen sections stained with darrow red–luxol fast blue. Only those animals with the lesion restricted to gracile nucleus are reported. In some, the extreme caudal end of the nucleus was spared.

Distribution of Receptive Fields

The distribution of receptive fields of cells in VPL was mapped in sixteen intact animals. In a further thirty-five animals maps were made of the intact VPL on one side so that these maps could be compared with those from the opposite VPL which had been partially deafferented by nucleus gracilis destruction. Successive recording points were distributed in a regular grid separated by 100 μm vertically and 200 or 250 μm rostrocaudally and mediolaterally. For each station on this three dimensional grid, the entire body surface was brushed with medium pressure and the position was noted of any area of skin which evoked unit responses with an amplitude greater than 50 μV.

In the normal VPL individual cells had small discrete receptive fields. Neighbouring cells recorded at a single electrode site had overlapping receptive fields restricted to some small area of the contralateral body surface. In 35% of the recording sites, cells responded to stimulation of trunk or proximal portions of the limbs or tail and these cells lie in the dorsolateral part of the nucleus. Twenty-four per cent responded to lower hind leg or feet or toes and lie ventrolaterally. Forty-one per cent responded to lower forearm or hands or fingers and are located ventromedially. The ventral surface of the nucleus is made up of a lamina about 200–400 μm thick which contains cells that respond to passive movement of the limbs. Ventral to the arm area these cells respond to arm movements and the cutaneous leg zone has leg movement cells ventral to it.

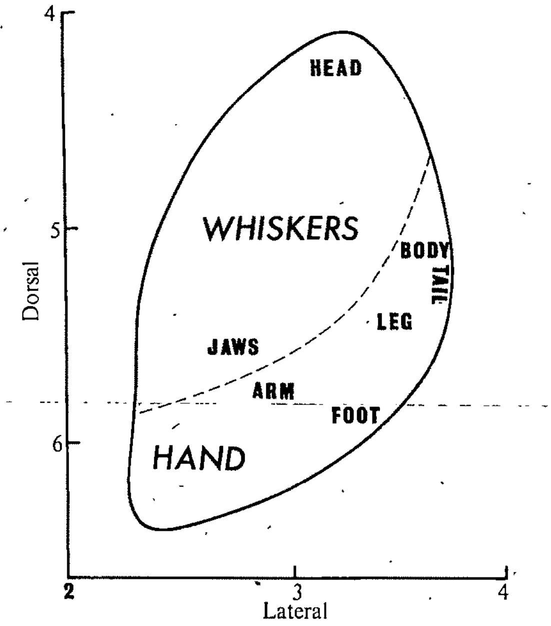

Fig. 1 Diagram of the representation in rat thalamus of the contralateral body surface. The region in which arm, trunk, leg and tail is represented in nucleus ventralis-posterior-lateralis. Maps are produced by placing microelectrodes successively at many locations in a single transverse plane in the region. For each recording point, the face and body surface is mechanically stimulated. Cells close to the recording electrode respond to a small area of skin. A combination of the receptive fields for all the points provides a map of the entire skin surface. The transverse plane is 4.5 mm rostral to external auditory meatus and the areas show distances in mm lateral to the midline and vertically below the cortical surface.

Cross-sectional maps were made first of one side and then continued across the midline to investigate the opposite nucleus. Fifty-seven pairs of maps were made in twenty animals at various stages after destruction of n. gracilis. Five variables were compared in the normal nucleus and its partner which had lost afferents: (1) the stereotactic coordinates of areas responding to particular parts of the body; (2) the ratio of the number of points on each side which responded to certain stimulus sites; (3) the monopoly by hind limb cells of the rostral pole of the normal nucleus; (4) the map in the ventral lamina of movement detection cells, which was unaffected by gracilis lesions and therefore provided another marker; (5) the receptive fields and latencies of selected single cells.

In rats mapped 1 or 2 days after destruction of the n. gracilis the picture is the same as immediately after the lesion (Fig. 2). The lower arm–hand–finger area is unchanged. In the leg–foot–toe region, there is an almost complete disappearance of sites where stimuli evoked activity. We shall describe the nature of these scattered responses to leg stimuli and those in the body region in another paper. In eight of nine animals mapped 3–17 weeks after the lesion, responses to stimuli on trunk, tail and hind leg remained essentially the same as in the acute and short survival animals but there was an expansion of the arm area into regions normally responding to leg stimuli. Sites responding to body and proximal limb stimuli averaged 25% fewer than normal, those for leg averaged 87.5% fewer but the number of arm points increased by 24%. Examination of the maps in detail shows that this expansion is produced by a lateral movement of the lateral edge while the medial part remains unchanged (Fig. 3). This lateral zone subserves the lower arm and wrist and these sites increased by an average of 132%. The change was most marked at the rostral pole where the zone normally monopolized by leg cells was now occupied by arm cells. Arm cells now lay dorsal to cells which responded to leg movement. The 16 and 17 week survival animals showed no greater expansion than the 3 week survivors. In no animal

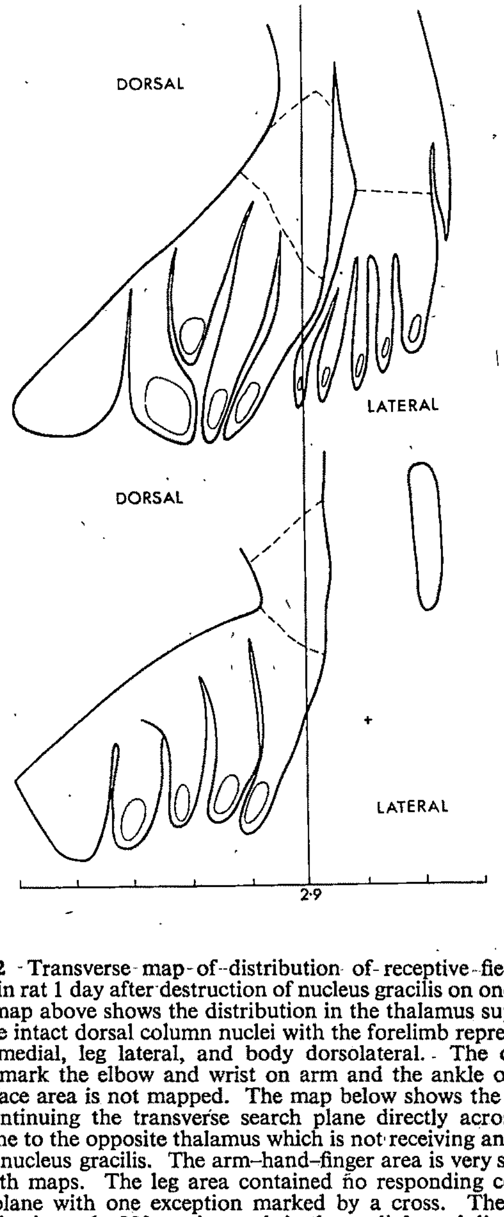

Fig. 2 Transverse map of distribution of receptive fields in VPL in rat 1 day after destruction of nucleus gracilis on one side. The map above shows the distribution in the thalamus supplied by the intact dorsal column nuclei with the forelimb representation medial, leg lateral, and body dorsolateral. The dotted lines mark the elbow and wrist on arm and the ankle on leg. The face area is not mapped. The map below shows the result of continuing the transverse search plane directly across the midline to the opposite thalamus which is not receiving an input from nucleus gracilis. The arm–hand–finger area is very similar in both maps. The leg area contained no responding cells in this plane with one exception marked by a cross. The horizontal axis marks 200 μm intervals in the mediolateral direction. The vertical line marks electrode tracks 2.9 mm from the midline penetrating both left and right thalamic maps. These tracks passed through the lateral arm region in each thalamus and show how similar the two arm regions are.

was the entire area which normally responded to hind limb invaded by the forelimb area. In a ninth animal with 3 week survival there were signs of expansion of the body area.

Time Course and Nature of the Change

The simplest explanation for the expansion would be the shrinking of deafferented cells with a simple moving over of the neighbours. In this case there would be no new connexions and the cortical somatotopic map would not be distorted. Successful maps were completed of the arm and leg area of main sensory-motor cortex on both sides in animals 2, 5 and 6 weeks after destruction of one n. gracilis. The animals were anaesthetized with urethane and the body surface stimulated as in the thalamic recording experiments. In order to obtain a sufficiently detailed map it was necessary to record the receptive fields of cortical units by penetrating 500 μm into cortex with glass, 2–4 Mohms, KCl filled microelectrodes. Maps were constructed from a grid of recording points separated by 500 μm. In all three animals, the arm area had expanded into the leg area and it must therefore be concluded that thalamic cells projecting to cortex had changed their peripheral receptive fields.

The simplest explanation for the appearance of new receptive fields would be that the deafferentation had unmasked existing afferents which are normally inhibited. This is unlikely because in this type of preparation even massive electrical stimuli to arm in the intact animal fail to excite cells with discrete receptive fields on leg. Furthermore, there is a time delay in the switching of receptive fields. During this period when the former leg cells fail to respond to peripheral stimuli, ongoing activity continues in them at at least the frequency of normally connected cells showing that the deafferented cells themselves do not go through a period of lowered excitability.

To postulate the formation of new connexions, it is necessary first to discover the time course of their development. Eleven animals were examined 1–7 days after the lesion. At 1 and 2 days there was no significant change. At 3 days, two of three animals showed some expansion but without invasion of the rostral pole. At 4 days one animal showed both expansion and rostral invasion while a second showed no change. Of two animals at 5 days, one showed the full picture of expansion and the other some expansion. A 6-day survivor was inconclusive but the 7-day animal showed the same full picture as those examined after 3 weeks. We conclude that the changeover begins at 3 days and is fully established between 1 and 3 weeks. The cell bodies of the changed cells lay 200–400 μm from the original boundary of the normal area but one must remember that the dendrites of the innervated and deafferented cells might be intermingled so that any shift of connexion might be over very small distances.

It is conceivable that the stimulus for the change of connectivity is not the degeneration of the terminals but the absence of the normal afferent impulses which bombard the thalamic cells. This possibility was ruled out by sectioning the dorsal columns just caudal to n. gracilis leaving the nucleus itself intact. The section of the fibres was made to spare the more lateral component of dorsal columns which supplies the cuneate nucleus. Thalamic maps from this animal taken 7 days after the lesion showed no signs of expansion of the arm area into the silent region which no longer responded to leg stimuli. It is true that the thalamus would still be bombarded by the ongoing activity of the deafferented nucleus gracilis but this is presumably slight by comparison with that transmitted in the normal freely moving animal.

A possible explanation for the newly effective connexion is that a background of ineffective fibres from the cuneate nucleus lie scattered through the area normally innervated by n. gracilis and that these fibres mature and successfully stimulate the cells vacated by degenerating axons. The change could be either presynaptic or postsynaptic. If such a diffuse system of fibres existed, one might expect the receptive fields of the newly connected cells to differ from those in the established part of the nucleus. In fact we were unable to differentiate the receptive fields of cells in the presumably newly invaded region from those medial to them either in terms of field size or threshold. It is a particularly suitable region for examining receptive fields because many cells respond to movement of one or more of the long whisker-like hairs protruding from the rat's volar wrist. Cells with precisely this type of receptive field seemed to be duplicated in the new territory. Another possible mechanism is that the cells respond to an indirect input perhaps by way of cortex rather than by way of axons originating in cuneate nucleus. This seems unlikely because the latency of response of the switched cells was identical to that in the unchanged zone.

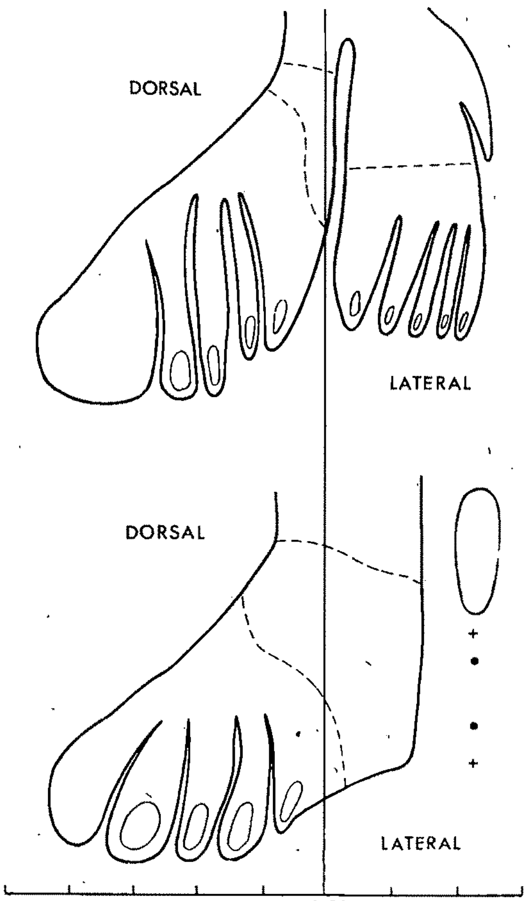

Fig. 3 Transverse map of distribution of receptive fields in intact VPL (above) and the map produced by continuing the mapping plane across the midline into the opposite VPL studied 7 weeks after destruction of the n. gracilis which projected to this nucleus (below). The vertical line marks an electrode track 2.8 mm from the midline which samples a similar region of the thalamus on the intact side to the vertical line shown in Fig. 2. The thalamus on the medial side of the line contains a similar map on both the intact and deafferented side. But the region representing the arm, especially the lower arm, has expanded on the operated side to invade a region which responds to leg on the intact side. At the lateral edge of the nucleus four cells were encountered which responded to body or leg stimulation but most cells in this region failed to respond to any peripheral stimuli.

Collateral Sprouting

Probably the most likely explanation is that sprouts have grown from the terminal arborization of intact axons from cuneate nucleus and have established successful contact with deafferented neighbours. Collateral sprouting and new contact formation have been shown to occur in the periphery both in denervated muscle[2] and in sympathetic ganglia[3]. In the central nervous system, light microscope evidence of sprouting into denervated regions has been provided for dorsal root fibres[4] and for optic nerve fibres[5]. Raisman[6] has shown clear electron microscope evidence for sprouting and end knob formation in the partially denervated septal nuclei of adult rat. But in the case of collateral sprouting, one must still explain the small receptive fields of the newly connected cells. The distance over which the sprouts would have to extend is not known, because although the cell bodies of the switched cells can be as much as 400 μm from the intact area it may be that the dendritic fields of the denervated cells overlap with those of the intact cells. If a sprout had only to grow a few-μm to occupy a new cell, a pioneer sprout might lay down a pathway along which its neighbours could grow. Another way in which a restricted receptive field might be formed would be if the fibres which fire together grow together. This would require a mechanism by which the presence of more or less coincident impulse traffic in terminals would exaggerate the growth of terminals which sensed impulses in themselves and their neighbours.

Clearly an explanation of the phenomenon reported here will have to await an electron microscope examination of morphological changes in the region of changed response. In assessing the significance of the phenomenon of new connexions, one must give certain warnings. These observations were made in the rat, an animal which continues to grow throughout adult life, perhaps therefore retaining certain embryological characteristics. The distance over which new connexions could be established is evidently limited since there were no signs of occupation of vacant cells in the lateral edge of the nucleus. The new connexions do not represent recovery from the original lesions because information from arms is now channelled into a system presumably specialized to handle leg information. However, one might speculate that if scattered single cells were destroyed, as in an encephalitis, sprouting from associated collaborating neighbours might provide some functional advantage.

Temperature Changes associated with Adiabatic Decompression in Geological Processes

D. R. WALDBAUM

Department of Geological and Geophysical Sciences, Princeton University

Joule-Thomson coefficients of crystals indicate that temperatures may increase during irreversible adiabatic release of pressure. Isenthalpic decompression provides a mechanism for "self-heating" in igneous and metamorphic processes.

When a substance is forced through a constriction in adiabatic conditions, the decompression is thermodynamically irreversible, occurring at constant enthalpy, *H*. For a normal fluid, the result may be either an increase or decrease in its temperature according to the initial and final pressures of the process[1-3]. Joule and Thomson[1] showed that the effect may be measured directly or calculated from the relation

$$\left(\frac{\partial T}{\partial P}\right)_H = \frac{V(T\alpha_P-1)}{C_P}$$

where T is thermodynamic temperature, P is pressure, α_P is isobaric thermal expansion $(1/V)\,(\partial V/\partial T)_P$, V is volume at P and T, and C_P is isobaric heat capacity.

This paper is concerned with the isenthalpic decompression coefficients (Joule–Thomson coefficients) of minerals, and their application to geological processes.

Decompression Coefficients of Crystals

For a crystalline phase, isenthalpic decompression produces an increase in its temperature inasmuch as $T\alpha_P \ll 1$. Table 1 lists values of $(\partial T/\partial P)_H$ at 1,000° C and 1 atm for minerals of basaltic and ultramafic rocks calculated from physical property measurements[4]. The sign and magnitude of the isenthalpic coefficients indicate that the temperature of a rock consisting of these minerals will change by approximately +220° C if the rock is decompressed across a pressure difference of 10 kbar by a strictly isenthalpic process, whether it be by extrusion or by some other mechanism.

For example, peridotite (or pyrolite) extruded from 20 kbar on an oceanic temperature–depth curve[5] to 10 kbar would be heated sufficiently to intersect an experimentally determined "dry" solidus for basalt or peridotite[6,7] (curve *A*, Fig. 1). Extrusion experiments by Bridgman[8] on antimony metal, discussed in the present context by Adams[9], suggest that a magma obtained by extrusion of crystalline rock might be ejected with nearly explosive force to still lower pressures, possibly to the surface.

It is relatively unimportant whether decompressed material melts or undergoes any phase changes. If decompression ends without a phase change, the heat exchanged between the decompressed material and its new surroundings may still cause anomalous heat flow at the surface[10] and phase changes (metamorphism) in the surrounding rocks.

The process represented by the isenthalpic decompression curve *A* in Fig. 1 does not differ in principle from the assumption that magmas can form as a result of the rapid release of pressure from material, so that its temperature subsequently intersects a melting curve from the high pressure side[11,12]. Such decompression requires at least a partially adiabatic process, otherwise the temperatures of the material would imitate those of the normal geothermal gradient. It is therefore usually implied that the pressure is released rapidly enough for the material moving upward to be always at a higher temperature than distant surrounding rocks at the same depth. But it is also assumed that the limiting maximum temperature in such a rapid release of pressure is that of an isentropic process[7,12] (for example, curve *B*, Fig. 1). Fig. 1 illustrates quantitatively that all forms of adiabatic decompression of minerals do not necessarily lead to cooling.

Table 1 Adiabatic Decompression Coefficients of Some Minerals

Mineral	Formula	$(\partial T/\partial P)_H$ (°K/kbar)
Spinel	Mg_2AlO_4	−21.0
Forsterite	Mg_2SiO_4	−23.7
Fayalite	Fe_2SiO_4	−23.0
Clinoenstatite	$Mg_2Si_2O_6$	−21.0
Diopside	$CaMgSi_2O_6$	−25.4
Jadeite	$NaAlSi_2O_6$	−23.2
Albite	$NaAlSi_3O_8$	−30.2
Anorthite	$CaAl_2Si_2O_8$	−29.6
Magnetite	$FeFe_2O_4$	−21.9
Chromite	$MgCr_2O_4$	−23.0
Corundum	Al_2O_3	−19.9
Periclase	MgO	−21.6
Rutile	TiO_2	−24.8
Graphite	C	−23.4
Diamond	C	−13.4
α-Iron	Fe	−13.2
Nickel	Ni	−18.9
Platinum	Pt	−29.1

The isentropic coefficient $(\partial T/\partial P)_S$, or "adiabatic gradient", is $+1.0 \pm 0.5$ K/kbar for these substances. Pressure does not significantly affect the above isenthalpic coefficients in the range of Fig. 1. The effects of temperature are important, and will be discussed in a later paper; for silicates, the isenthalpic coefficients decrease by about 20% from 500° to 1,500° C. The effects of *P* and *T* are small enough that the above values serve as good estimates of the slopes of the true isenthalpic *P*, *T* curves from 800° to 1,200° C, in which case the line connecting the initial and final pressures of an irreversible decompression process is nearly coincident with the isenthalp itself.

It should not be inferred that a single stage isenthalpic process is required to produce heating. In any complex geological environment, when adiabatic decompression occurs, it is likely to consist of a series of isenthalpic and isentropic steps as shown by curve *C* in Fig. 1. A process involving only a small fraction of isenthalpic decompression steps could still result in an increase in temperature because

$$|(\partial T/\partial P)_H| \gg |(\partial T/\partial P)_S|$$

Recognizing that both isenthalpic and isentropic decompression represent limiting aspects of an adiabatic process, and that many other factors may affect the net result of pressure changes in geological processes, there are other geological situations where the isenthalpic contribution may be significant.

It is emphasized that the thermodynamic coefficients in Table 1, as with any thermodynamic property, may be applied to real or hypothetical processes whose physical mechanisms differ considerably in detail. It is not necessary to limit the application of isenthalpic decompression to conditions of high-velocity flow[1,2,9]. The only condition to be met is conservation of enthalpy in the material undergoing decompression.

Flow Processes

Extrusion and throttling are examples of a large class of phenomena where a stationary flow is maintained in an isolated part of a mass bounded by streamlines, or through a tube of varying cross-section (as, for example, in the mantle convection model of Turcotte and Oxburgh[13], although they assume an isentropic model). Enthalpy remains constant along such an adiabatically enclosed "tube" of flowing material[3,14]. The isenthalpic coefficients of minerals indicate that the temperature of an isolated mass will rise during decompression and flow, even in the idealized case where friction, viscosity, and turbulence are ignored.

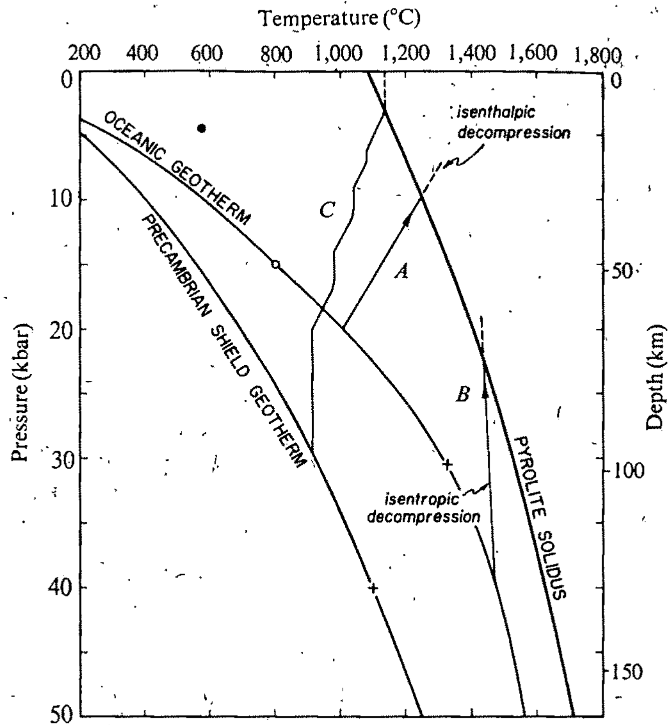

Fig. 1 Diagram comparing isenthalpic decompression (*A*), isentropic decompression (*B*), and a composite decompression curve (*C*) for a rock consisting of silicate minerals in Table 1. Temperature–depth curves are taken from ref. 8; the curve representing beginning of melting of pyrolite III composition is taken from ref. 10. The decompression curves are extended as a dashed line beyond their intersection with the melting curve, due to possible complications and uncertainties in the enthalpies of fusion, physical properties of the fluid, and the rate of migration of the fluid from the point of extrusion. Open circle denotes minimum depth from which decompression could cause a rock of pyrolite composition to begin melting in the absence of water. Small dot represents andalusite–kyanite–sillimanite triple point. Crosses indicate approximate depths from which forsterite would have to be decompressed at constant *H* to form a liquid at or near the surface.

The sign and magnitude of the isenthalpic coefficients thus provide a possible quantitative thermodynamic basis for the close association often observed between deformation, regional metamorphism, and partial melting of sedimentary rocks[15,16]. The values are such that the observed effects of regional metamorphism can be obtained without necessarily requiring the addition of energy from external sources such as magmatic intrusions, by fluid transfer[17], or by frictional heating[18]. The effects of adiabatic decompression, however, are only likely to be of importance in those areas where evidence for forced flow can be demonstrated[19]. Dewey and Pankhurst[16] summarized studies on the distribution of metamorphic temperatures in time and space in the final episode of the Caledonian orogeny. The form of the proposed geothermal curves and their variation in time are consistent with a possible origin by isenthalpic flow. Similar observations summarized by Niggli[20] and Wenk[21] for the last stage of orogenic activity in the Central Alps may also be interpreted in this way.

As with any extrusion process, the resultant increase in metamorphic grade from simple isenthalpic decompression will depend on the initial temperature and pressure, the pressure difference causing flow, and the energy required for phase changes within the rock mass. Models of regional metamorphism based on thermochemical fluid dynamics will probably yield more satisfactory results than those based on a simple heat conduction model for an igneous intrusion[22].

Considering the emplacement of alpine-type ultramafic rocks from this viewpoint, the observations of Raleigh[23], Dickey[24], and others may be extended to include the possibility that some peridotites and dunites originated as "peridotized" serpentinites[25] (which later reserpentinized, in part). Serpentine has an isenthalpic decompression coefficient of 26° C per kbar of differential (hydrostatic) pressure at 500° C, and calculations based on thermodynamic data[4] support the hypothesis of Carpenter and Phyfer[25]. An isenthalpic decompression of 9 kbar of partially serpentinized peridotite (initially one part serpentine to one part olivine by volume at 550° C and 10 kbar) yields an anhydrous peridotite at 1 kbar and 670° C. This result includes the conservation of enthalpy in dehydrating serpentine to less hydrous or anhydrous phases during decompression.

Isenthalpic decompression may be a mechanism in the lunar interior where heat sources of sufficient magnitude have not yet been conclusively identified for producing magma[26]. This mechanism may contribute significantly to the formation of subsurface magma associated with the impacts of large meteorites[27] that produce fractures through which solid material might extrude. This mechanism allows for the possibility of early or recent lunar volcanism in a way that does not conflict with the hypothesis that the interior of the Moon has been relatively cold since the early stages of its formation. A similar mechanism could account for the origin of subsurface-derived magmas associated with the Sudbury (Canada) complex[28] and other terrestrial structures[29] thought to have resulted from meteorite impacts.

Shock Decompression

Another possible isenthalpic decompression process is that which occurs during the passage of a shock wave in a solid, although it is sometimes assumed, by analogy with the behaviour of gases, that compression alone causes the heating. Shock compression and decompression are largely adiabatic and irreversible, so these processes may occur at constant enthalpy. For example, any of the silicates in Table 1 would cool from room temperature to near absolute zero with only 12 kbar of compression at constant H (if such a process occurs). Enthalpy is gained, however, in the transfer of kinetic energy to the solid, so that very low temperatures may never be reached, but any net temperature rise on compression will be small. Subsequent decompression of only 100 kbar would form the high temperature crystalline phases and vesicular glass observed in shock-wave experiments on anhydrous minerals[30]. Igneous rocks associated with impact structures[28,29] may thus originate from two possible isenthalpic processes: shock decompression acting on the surface rocks and extrusion leading to melting at depth.

Isenthalpic shock-decompression may also cause magma to form from crystalline rock *in situ* at depth in seismically-active zones. The shock pressures required for high residual temperatures may be much less than previously estimated[29,31] if attributed to isenthalpic rather than isentropic decompression.

To summarize, the sign and magnitude of the coefficients in Table 1 indicate that any process leading to a completely or partially isenthalpic decompression of minerals can, at least in principle, lead to an increase in their temperature. The prevailing opinion that the adiabatic parts of geological processes are entirely isentropic (reversible) requires some reconsideration. They are also likely to be irreversible in part, in which case data such as those in Table 1 apply. It should be possible to explore these hypotheses in decompression experiments[32] by attempting to duplicate the textures and mineralogy found in some of the geological environments described here. Some use could be made of high-pressure mineral synthesis or rock-deformation experiments that terminated unexpectedly by rapid decompression. Detailed petrographic study of these "unsuccessful" run products should yield information on textural and kinetic aspects of decompression that cannot be predicted by thermodynamics alone.

I thank R. B. Hargraves, R. E. Openshaw, L. M. Cathles, and L. S. Hollister for comments on the manuscript.

Ehrenfest's Paradox

ATWATER's remarks[1,2] on the relativistic rotating disk problem (Ehrenfest's paradox[3]) have elicited considerable response[4–6] of a somewhat peripheral nature. Atwater concludes that recourse to experiment is highly desirable. Arzelies[7], while questioning the existence of relativistic constraints, also agrees with this view. The purpose of this communication is to point out what one might expect to observe as a disk rotates and to develop the magnitude in a practical case.

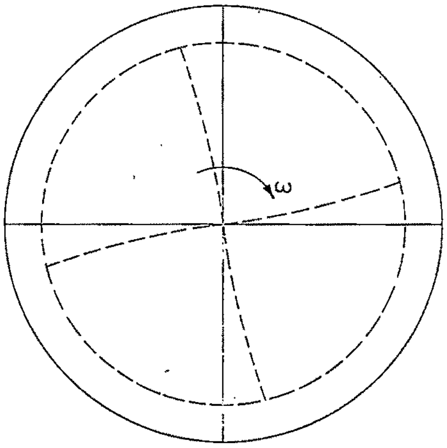

Fig. 1 A schematic representation of the rotating disk.

Suppose we have a disk of radius a rotating clockwise with angular velocity ω about an axis through its centre perpendicular to its plane. Take a radial element of the disk at distance r from the centre and consider a small section Δr along r. Then after one revolution, this section must have rotated counterclockwise with respect to its direction along r in consequence of the Thomas precession[8].

It is easy to see that this angle (in radians) is given by

$$\delta\theta = \pi \frac{\omega^2 r^2}{c^2} \qquad (1)$$

per revolution. Integrating along the whole element, we find it deflected counterclockwise by an angle

$$\theta = \frac{\pi}{3} \frac{\omega^2 a^2}{c^2} \qquad (2)$$

per revolution.

Thus the appearance of the disk to a fixed observer will be as shown by the dotted lines in Fig. 1. It will be noted that the disk is in torsion with consequent reduction of both radius and circumference. Thus the premises leading to the Ehrenfest paradox need not exist. This description should not be any more surprising than the well observed time dilation. A rotating disk is clock-like in character with the Thomas precession giving an accumulating measure of the number of revolutions. Further, the effect should be independent of the disk material, just as an equivalent clock is independent of its construction.

The relativistic constraints just introduced do, moreover, imply physical consequences for rotating bodies such as the Earth, pulsars, and so on, but this is considered elsewhere (D. H. W. and J. W. Kern, to be published). I wish to make clear that a practical laboratory experiment is entirely possible.

Take, for example, a disk 10 cm in diameter rotating 1,000 r.p.s. Then equation (2) yields $\theta \sim 10^{-12}$ per revolution. For a period of 30 days $\theta \sim 0.16°$. This should be well within currently available means of measurement when the position of a point on the circumference is compared with a point near the axis.

This measurement might be conveniently carried out, for example, by placing a fiducial mark on the edge of the disk with a similar mark in the stationary frame adjacent to the edge. These marks can then be compared during rotation when illuminated by a discharge lamp triggered by a sharp magnetic pulse, or other means, positioned at a radial distance b on the disk. This will modify equation (2) and it then becomes

$$\theta = \frac{\pi}{3}\frac{\omega^2}{c^2} a^2 \left(1 - \frac{b^2}{a^2}\right) \qquad (3)$$

per revolution.

With the passage of time, the mark on the disk will appear to move away from the fixed mark in accordance with equation (3) and counter to the direction of rotation.

Geomagnetic Dynamos in a Stable Core

Higgins and Kennedy[1] have suggested that the Earth's core is in stable equilibrium. If this is so there cannot be the large scale steady motions with a radial component which have usually been thought necessary for the dynamo theory of the Earth's magnetic field. A stable fluid can have internal wave motions and it seems worth considering whether a body of fluid can act as a dynamo and produce steady electric currents and magnetic fields even when the motion is purely oscillatory. The work of Moffat[2,3], Roberts[4] and Steenbeck and Krause[5] shows that this is so in an infinite fluid and it seems likely that it will be true in a sphere. The discussions of fluid dynamos are necessarily complex and we have therefore considered the very simple case of an oscillatory disk dynamo. This dynamo consists of a disk oscillating about its axis of symmetry with a coil connected to brushes on the axle and at the edge of the disk. Any current in the coil will produce a field, the motion of the disk in the field produces a current in the coil and maintains the field. The equation for the current, I, in such a system is easily shown to be[6]

$$L\dot{I} + RI = M\Omega I \qquad (1)$$

where L and R are the inductance and resistance of the circuit, $2\pi M$ is the mutual inductance of the coil and the disk and Ω is the angular velocity of the disk. The equation bears an analogy to Maxwell's equations for the field, $\mathbf{B}$, in a fluid of conductivity σ and permeability μ moving with velocity $\mathbf{v}$, which give

$$\dot{\mathbf{B}} - \nabla^2\mathbf{B}/\mu\sigma = \text{curl}\ (\mathbf{v}\times\mathbf{B}) \qquad (2)$$

In both cases the question is, can the interaction of the motion and the field, the term on the right, balance the second term on the left to give an average $\dot{I}$ or $\dot{\mathbf{B}}$ which is zero or positive ? If the motion is oscillatory the answer will depend critically on the relative phase of the motion and the current or field, that is of Ω relative to I in equation (1) or $\mathbf{v}$ relative to $\mathbf{B}$ in equation (2) (the mean of $\cos t \sin t$ is zero, but the mean of $\cos^2 t$ is $\frac{1}{2}$). The study of equation (2) needs elaborate mathematical techniques, since $\mathbf{B}$ is a function of space as well as time. For equation (1), however, there exists an elementary solution; it shows that the phase relations are wrong and that the current is not maintained. It is known, for steady motion, that two coupled disk dynamos with the current from each feeding the coil of the other possess properties not shown by the single dynamo[7,8]. We have studied such a system with oscillating disks and have shown that a current with a steady part may be maintained or caused to grow exponentially so long as some Fourier component of the oscillations of one disk is out of phase with the corresponding component of the motion of the other.

The simplest case is when each disk performs simple harmonic oscillations, the phase difference between the two being $\frac{1}{2}\pi$. The decay time of the current in the absence of motion is L/R, if this is large compared with the period of oscillation of the disks, then one coil has a steady current with a small ripple superposed and the other a much smaller alternating current. The calculations, which are very simple, suggest that dynamos with steady fields and oscillatory motions may exist in a wide variety of circumstances. Higgins and Kennedy, therefore, may not have seriously embarrassed the dynamo theory, even if their main contention is correct, as seems likely.

The detailed calculations will appear in a forthcoming book[9].

Variations in Magnetic Intensity and Climatic Changes

CORRELATION between the variations of the Earth's magnetic field, fluctuations in atmospheric radiocarbon activity, and climatic changes during the past 7,000 yr has been discussed extensively in the past[1-7]. In addition, Harrison[8] has suggested that reversals of the Earth's magnetic field could cause climatic changes. With an associate we have recently[9] been able tentatively to conclude on the basis of studies of deep-sea sediment cores that in the past 470,000 yr the magnetism of the Earth has modulated climate. We have now extended the correlation between variations of the magnetic intensity and evidence of climatic change from deep-sea sediment cores back to 1.2 m.y.

Many investigators have studied remanent magnetism in deep-sea sediment cores[10-15]. The study was conducted according to the method of Opdyke *et al.*[11]. The cores on which the remanent magnetism was measured were sampled at intervals of 2 to 10 cm and dried samples were cut into rough cubes measuring approximately 2 cm. Reversals were detected by finding the inclination of the remanent field of the series of samples with respect to the axis of the core. The samples were partially demagnetized in an alternating field of 150 oersted to remove unstable components.

Table 1 Details of the Cores that were Investigated

Core	Latitude (N)	Longitude (W)	Depth (m)	Length (cm)	Sedimentation rate (cm per 1,000 yr)
V12–122	17° 00′	74° 24′	2,800	1,090	2.32
V20–108	45° 27′	179° 14′	5,625	1,320	1.10
V26–41	19° 19′	26° 06′	4,340	1,400	1.16

The cores (Table 1) consist of a mixture of fine mineral particles and particles of calcium carbonate, except that core V20–108 contains no calcium carbonate.

Our climatic study is based on measurements of the abundance of the *Globorotalia menardii* group of planktonic foraminifera, including the four subspecies *G. menardii menardii*, *G. m. tumida*, *G. m. flexuosa* and *G. m. fimbriata*. Although Emiliani[16], on the basis of a study by Lidz[17], has maintained that the *G. menardii* group is unreliable as a climate indicator, we believe[18] that Lidz's conclusion is misleading and that as a consequence, Emiliani's conclusion is ill-formulated. Therefore, like others[19-21], we have taken the *G. menardii* group to be reliable for the study of climatic changes in most deep-sea sediment cores, with abundance indicating warm climate.

Fig. 1 shows correlation of the magnetic intensity curve of deep-sea sediment core V20–108 from the North Pacific, the *Globorotalia menardii* climate curve in core V26–41 from the North Atlantic, and the oxygen isotope climate curve of *Globigerinoides rubra* measured by van Donk[22] in core V12–122 from the Caribbean. The magnetic intensity measurements in core V20–108 are according to Ninkovich *et al.*[12] and Foster[23] with adjustment for the stretched out top section. Because this core contains no calcium carbonate we cannot make foraminiferal measurements of the climatic changes. The time scales for cores V20–108 and V26–41 are based on magnetic reversals at the Matuyama–Brunhes boundary and at the Jaramillo event. The age for the Matuyama–Brunhes boundary is given by Cox and Dalrymple[24] who consider that the most probable age for this boundary is 0.69 m.y. The age and duration of the Jaramillo event is given by Opdyke[25] who places the upper boundary at 0.86 m.y. and the lower boundary at 0.92 m.y. with a duration of approximately 60,000 yr. The palaeomagnetic stratigraphy of core V20–108 was determined by Ninkovich *et al.*[12] and by Foster[23] and of core V26–41 by Opdyke (personal communication). The time scale for core V12–122 was determined by Broecker and van Donk[26] based on thorium-230 dating by Ku and Broecker[27]. It is in general agreement with the protactinium dating of the same core by Sackett[28].

Because the intensity measurements in core V20–108 are per gram of sediment and not per gram of magnetizable material in the samples, some of the variability in the intensity measurements in the core may be due to differences in composition and abundance of magnetic minerals in the sediment samples. Although the magnitude of the remanent magnetic moment in the core may be related to a change in the sedimentary sequences brought about by dilution of detrital components by biogenic components, it is difficult to imagine a scheme in which the direction[9] of the recorded magnetic vector is changed systematically through depositional processes.

The changes in the sedimentary sequence in the North Pacific core, V20–108, which contains no calcium carbonate, could have been brought about by an influx of ice-rafted detritus which could have introduced a greater abundance of magnetic minerals in the cold periods. Therefore, we have plotted variations in magnetic intensity in this core against weight percentages of sediment coarser than 250 µm in particle diameter measured by Kent *et al.*[29]. According to these authors this size fraction has been transported by icebergs.

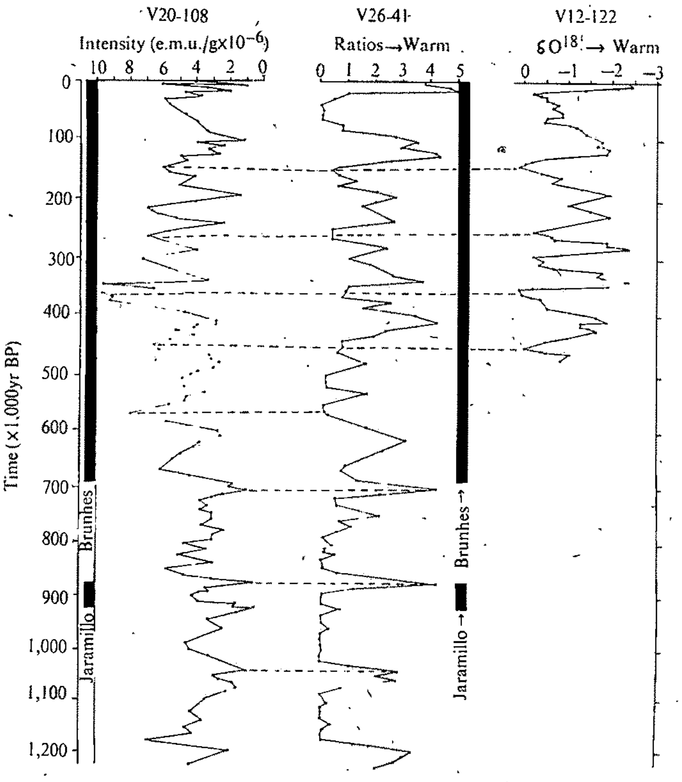

Fig. 1 Correlation of the magnetic intensity curve of deep-sea sediment core V20–108 from the North Pacific, the *Globorotalia menardii* climate curve in core V26–41 from the North Atlantic, and the oxygen isotope climate curve of *Globigerinoides rubra* measured by van Donk[22] in core V12–122 from the Caribbean. The magnetic intensity measurements and the magnetic stratigraphy of core V20–108 are according to Ninkovich *et al.*[12] and Foster[23] with adjustment for the stretched out top section. Because this core contains no calcium carbonate we cannot make foraminiferal measurements of the climatic changes. The magnetic stratigraphy of core V26–41 was determined by Opdyke (private communication). The time scales for cores V20–108 and V26–41 are based on magnetic reversals at the Matuyama–Brunhes boundary and at the Jaramillo event according to dating of the boundary by Cox and Dalrymple[24] and dating of the event by Opdyke. The time scale for core V12–122 was determined by Broecker and van Donk[26] based on thorium-230 dating by Ku and Broecker[27].

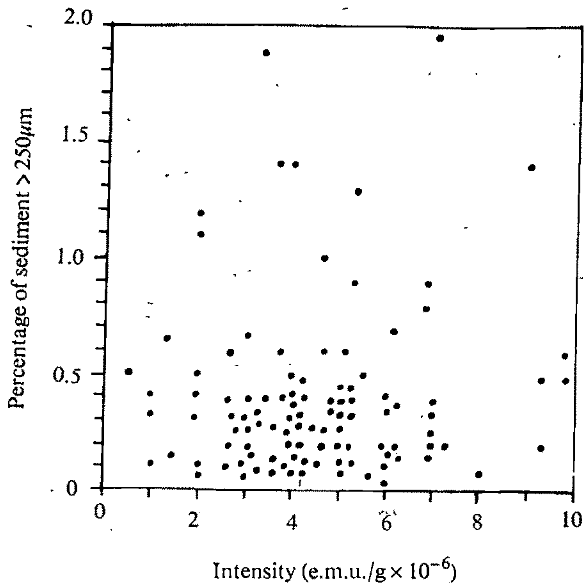

Fig. 2 Scatter plot showing that there is no correlation between magnetic intensity variations and changes in the sedimentary sequence in deep-sea sediment core V20–108 from the North Pacific. The changes in the sedimentary sequence could have been brought about by an influx of ice-rafted detritus which could have introduced a greater abundance of magnetic minerals in the cold periods. Therefore, we have plotted variations in magnetic intensity against weight percentages of sediment coarser than 250 µm in particle diameter measured by Kent *et al.*[29]. According to these authors this size fraction has been transported by icebergs.

As Fig. 2 shows, there is no correlation between the magnetic intensity variations and changes in the sedimentary sequence.

On the basis of the results shown in Fig. 2 we suggest that the intensity measurements in core V20–108 may represent meaningful approximations of changes in the intensity of the Earth's magnetic field although we have not attempted to estimate the percentages of magnetizable material in the core.

We have shown correlations between variations in magnetic intensity and climatic changes. On the basis of evidence reported here and additional evidence[9] we suggest that cause and effect relationship links changes of the Earth's magnetic field and climate. For instance, higher magnetic intensity seems to indicate colder climate. Thus we conclude that magnetism may modulate climate to some degree by the ability of the Earth's magnetic field somehow to provide a shield against solar corpuscular radiation.

We thank M. Ewing, J. Kukla, N. D. Opdyke, W. Pitman III, Bruce C. Heezen, J. van Donk, A. W. H. Be', D. Horn, J. H. Foster, and B. Horn for help, and Janet Wollin and Julie McGowan for assistance in laboratory investigations. The research was supported by the US National Science Foundation.

Spontaneous Fission of Heavy Transuranium Elements in the Surface Layers of the Peculiar A Star HR 465 explains Promethium Abundance

THE possibility that transuranium elements are present in the surface layers of peculiar A stars was raised last year[1,2] after Jaschek and Malaroda[3] announced evidence for the presence of uranium lines in the Ap star 73 Dra. Further information about the abundances of transbismuth elements in peculiar A stars is now available[4–6] and there is strong evidence[7,8] for the presence of promethium lines in the peculiar A star HR 465. All these facts imply, in the framework of the Guthrie–Van den Heuvel theory of the origin of Ap stars[9,10], that a search for transuranium elements in the spectra of those stars, at least in those in which uranium or promethium has been detected, should give positive results. It may even be possible to find the spectral lines of superheavy elements from the island of stability[11] near $Z=114$.

The implications resulting from the presence of uranium are self-explanatory[1,2] whereas this is not so if promethium is present. We therefore present some qualitative arguments in favour of our hypothesis that the promethium which is observed in HR 465 is continually produced in the spontaneous fission of very heavy transuranium elements, possibly superheavy elements which have been sought for in numerous experiments.

The longest lived promethium isotopes, ^{145}Pm ($T_{1/2}=17.7$ yr) and ^{146}Pm ($T_{1/2}=5.55$ yr), are neutron-deficient and cannot be produced in any neutron capture chains. The other Pm isotopes which could have been produced in the r process have even shorter half-lives. It is thus unrealistic to attribute the promethium abundance in the Ap star HR 465 to fast neutron capture which occurred either in the primary star of the binary system or in the surface of the recent peculiar star. The amount of promethium that should have been produced could not survive until now. We could think about some kind of continual production of promethium in surface reactions either with helions or with protons that might be accelerated in areas of high magnetic field density. This would be some *ad hoc* extension of previous concepts[12,13] and it seems very improbable. From a detailed analysis of the various possible production modes of Pm (Kuchowicz, work in preparation) it seems that only spontaneous fission of very heavy nuclides provides a natural mechanism for this. This is because the two promethium isotopes ^{147}Pm and ^{149}Pm, with half-lives of 2.62 yr and 53.1 h, respectively, occur in isobaric decay chains of fission products. An interesting result from a recent analysis of the product yield curves for fission of various nuclei[14] is that the total yield for the chains involving promethium is approximately constant (about 2% for $A=147$, and 1% for $A=149$) for light transuranium elements. For heavier elements, up to the additional island of stability near $Z=114$, it is expected that the light mass peak in the mass distribution of fission fragments is shifted towards the heavy peak, and symmetric fission occurs. This enhances the yield of isobaric chains including promethium, and it may be even as high as 5%.

We thus see that promethium cannot be regarded as a rare fission product of the heavier fissioning nuclei. Provided large amounts of such nuclei were produced in the exploding primary component of the binary system[10] and then they were transferred to the surface of the recent Ap star, they are a continuous source of promethium. It is important to notice that all superheavy nuclides eventually decay to spontaneously fissioning nuclei, and thus a final result of their initial presence in any material is an enrichment of the fission products in that material. Thus Dakowski[15] proposed that the symmetric fission of superheavy nuclei may account for the anomalies in the isotopic compositions of Xe and Kr in meteorites. It cannot be excluded that the overabundances of certain rare earths in the Ap stars of the main group may be attributed to a similar reason.

It is important to know the initial abundance of superheavy nuclei in the surface matter of Ap stars. The synthesis of these elements in the r process is well understood. Schramm and Fowler[16] obtained recently an abundance of ~ 0.6 for the eight long-lived superheavy nuclei with half-lives exceeding 10^3 yr (on the scale with $\mathrm{Si}=10^6$). Thus if we know the promethium abundance in HR 465, it will be possible, in principle, to calculate from it the concentration of the superheavy nuclei in the atmosphere (which may exceed by many orders of magnitude the concentration of Pm).

An important conclusion of our reasoning is that promethium may also be present in other peculiar A stars, especially in those where uranium has already been found. Its abundance should be correlated to the occurrence of r-process elements. This should be confirmed by observation. It may also be possible that superheavy elements can be found in at least some of the peculiar A stars in which promethium will be present. With these elements regarded as a continuous source for promethium, we can hope that they still exist in observable amounts. It is only the lack of knowledge of their optical spectra that makes us unable, at present, to make a search for their lines in the spectra of peculiar A stars. It may be expected that in the future this can be overcome, but even now the observation of promethium seems to confirm the existence of superheavy elements suggested on the basis of other data by Marinov *et al.*[17] and by Bhandari *et al.*[18].

Tungsten-181 and Other Short Lived Fission Products in Ground Level Air in North Germany and North Norway

SAMPLES of atmospheric dust have been collected for several years at 1.5 m above ground in Brunswick (52° 18′ N, 10° 28′ E) as part of an environmental radioactivity surveillance programme. Before analysis, each filter, made from 'Microsorban' (Delbag, Berlin) is ashed at 450° C. The content of fresh fission products in the samples is then measured in a 10 cm by 10 cm NaI(Tl) well-type scintillation spectrometer. Later, the ashes of all filters exposed during half a month—containing dust from about 50,000 m³ of air—are combined and measured in a 45 cm³ well-type Ge(Li) detector with a multichannel analyser (ND 2200). The activity concentrations of various fission products and certain cosmogenic radionuclides are evaluated from the γ-spectra numerically. Since October 1970 a filter sample containing dust collected from about 300,000 m³ of air in Tromsö (Norway) is also analysed once a month. Within recent months fresh fission products were detected on three occasions.

First, 10 days after the eleventh nuclear test of the Chinese People's Republic (October 14, 1970) ^{131}I was found in a rain sample, dated October 24–25, 1970. The concentration was 2 pCi/l.; during the following days, dust samples both from Brunswick and Tromsö contained ^{140}Ba+^{140}La, ^{147}Nd and ^{237}U. In Brunswick the concentrations were 1.8, 1.2 and 3 fCi/m³ ± 20%, respectively. The activity concentrations of some other radionuclides are listed in Tables 1 and 2. The increasing ratio ^{103}Ru/^{106}Ru from 0.1 in October 1970 to 1.0 in late March 1971 (Brunswick) implies that most of these Chinese fission products reached the surface layer through the stratosphere during the spring peak.

Second, dust samples collected between December 24, 1970, and January 2, 1971, in Tromsö, and between December 30, 1970, and January 2, 1971, in Brunswick contained ^{131}I and, in very low concentrations, ^{132}Te and ^{140}Ba+^{140}La, probably produced by the United States underground nuclear test, Nevada, December 16, 1970.

Third, between April 2 and 6, 1971, ^{140}Ba+^{140}La was found in Brunswick; by Ge(Li) spectrometry of the combined ashes of the filters exposed between March 31, 1971, and April 16, 1971, in Brunswick, ^{181}W was also detected with a mean activity concentration of 0.27 fCi/m³ ± 20% (for quantitative evaluation the Ta K X-ray peaks were used); before and after this time interval, no ^{181}W was detectable. The filter exposed in Tromsö during the same month also contained ^{140}Ba+^{140}La as well as ^{181}W, the latter with a concentration of 0.38 fCi/m³ ± 20%.

Relative standard deviation = ±5%.

In December 1968 tungsten-181 was found in ground level air in Italy[1], Finland[2] and the United Kingdom[3], after an underground nuclear test carried out in Nevada on December 8, 1968. The origin of the small ^{181}W contamination detected in early April this year in North Germany and North Norway is still unknown.

Newspapers reported two USSR underground tests on March 22, 1971, in Siberia and on March 23, 1971, in the western Ural Mountains. At that time there was a prevailing westerly wind between Central Europe and the Ural region. If there was any venting into the atmosphere nuclear débris must have been transferred at first in easterly directions. Some days later a high pressure system arose over eastern Europe and led easterly winds to North Germany in early April, the time at which fresh fission products arrived at Brunswick. So it cannot be excluded with certainty that these fission products as well as ^{181}W stem from one of the above mentioned USSR underground tests.

Composition of Airborne Lead Particles

Knowledge of the composition of airborne particles and the reactions that take place in the atmosphere is important to the understanding of the fate of these particles. Lead compounds are present in a concentration of about 1% in the particulate and information about their composition would be especially helpful to people conducting experimental studies on the health effects of lead in air.

Hirschler *et al.*[1] have shown that the chief lead products exhausted from automobiles are lead halides and ammonium lead halides; lead chlorobromide is the principal component. The automobile is the principal source of airborne lead[2]. The fate of these materials and the changes in chemical composition in the atmosphere have been poorly understood. Work done by the Stanford Research Institute, using electron and X-ray diffraction, showed that most of the lead compounds in the atmosphere were amorphous or present in such low concentrations that identification was nearly impossible[3]. Their work further showed that the mass median diameter of airborne lead particulate is about 0.25 µm (ref. 4).

In our study, airborne particulate lead compounds were physically identified by using an electron microprobe (an ARL type EMX modified to give an electron spot size of the order of 0.2 µm). Samples were taken from a controlled environment, near and at a distance from a busy highway, and in a rural area.

Airborne particulate was collected on 0.45 µm 'Millipore' membrane filters, which were dissolved in acetone and the particles were centrifuged out of the resulting solution. The particles were then mounted in a film of nitrocellulose on ultrapure polished beryllium substrates, coated with about 300 Å of carbon. Beryllium was chosen because it has very low white radiation and no line interference with the elements of interest. The thin film of carbon eliminated any reaction with lead bromides, but did not interfere with the analysis.

All the analytical work was based on analysis by ratios of elements rather than by absolute intensities. This was necessary both because of the small particle size and because of the time allotted for data acquisition. It was possible to pick out the various classes of compounds apparently present and then return to individual particles known to be this compound—or at least suspected to be this compound—and analyse them in more detail. Several particles from each class of compounds and each sample were analysed in detail in this way.

Samples of airborne particles were collected near to and about 400 yards from Eight Mile Road, a state highway on the northern edge of Detroit that carries about 100,000 cars each day. Samples were also taken in a rural area about 400 yards from a very lightly travelled roadway that is 15 miles from the nearest city (population 25,000). The samples taken near the highway and at 400 yards from the highway contained about 2.6% and 1.2% lead respectively. The rural sample contained a few tenths of a per cent lead.

Samples were also taken of automobile exhaust; these were collected in a black bag—a 4,000 foot^3 plastic container filled with clean dry air. For the study, 300 feet^3 of exhaust gas taken from an automobile operating on the seven-mode Federal Cycle was passed into the bag. The ten-fold dilution prevents condensation. Samples for analysis were taken immediately after automobile exhaust was discharged into the black bag and 18 h later. The particulate samples from the bag were about 25% lead. They had a size distribution similar to that found in atmospheric samples.

Table 1 Sample Composition by Electron Microprobe

	Percentage of total particles counted													
Sample	$PbCl_2$	$PbBr_2$	PbBrCl	Pb(OH) Cl	Pb(OH) Br	$(PbO)_2$ $PbCl_2$	$(PbO)_2$ $PbBr_2$	$(PbO)_2$ PbBrCl	$PbCO_3$	Pb_3 $(PO_4)_2$	PbO_x	$(PbO)_2$ $PbCO_3$	PbO · $PbSO_4$	$PbSO_4$
Black bag														
Zero time	10.4	5.5	32.0	7.7	2.2	5.2	1.1	31.4	1.2	—	2.2	1.0	—	0.1
18 h	8.3	0.5	12.0	7.2	0.1	5.6	0.1	1.6	13.8	—	21.2	29.6	0.1	—
Eight Mile Road														
Near road	11.2	4.0	4.4	4.0	2.0	2.8	0.7	2.0	15.6	0.2	12.0	37.9	1.0	2.2
400 yards	10.5	0.7	0.6	8.8	1.1	5.6	0.3	0.6	14.6	0.3	25.0	21.3	4.6	6.0
Rural site	5.4	0.1	1.6	4.0	—	1.5	—	1.0	30.2	—	20.5	27.5	5.0	3.2

Table 1 shows the electron microprobe data for the samples. Individual sizes from 0 to 0.2, 0.2 to 0.6, 0.6 to 2, and greater than 2 µm were examined. Because the composition distribution was so similar for all sizes, the sample data were averaged.

Examination of the data for exhaust gas from the black bag is very informative. At zero time, a significant percentage of the exhaust particles consists of $PbBr_2$, PbBrCl, Pb(OH)Br, $(PbO)_2PbBr_2$ and $(PbO)_2PbBrCl$. Some intermediate halides might also be present up to concentrations of 10%. After 18 h, about 75% of the bromide is gone. About 30 to 40% of the chloride compounds also appear to have been lost. The products formed are lead carbonates, oxycarbonate, and oxides. Basic lead carbonate may be the actual product rather than the oxycarbonate. As water is easily lost from these compounds in the electron beam, however, the product identified is the oxycarbonate. It is estimated that the particles examined contained less than 1% of cations other than lead.

The loss of bromine was confirmed using X-ray fluorescence to measure the ratio of bromine to lead in the particulates in the black bag. The ratio rapidly decreased with time, with most of the loss occurring during the first hour.

When the composition in the black bag at 18 h is compared with the samples taken from the atmosphere, striking similarities are apparent. The sample taken near Eight Mile Road still contains significant quantities of bromide, although not as much as in the black bag at zero time. On the other hand, the sample taken away from the road contains almost no bromide and is very similar in composition to the black bag sample at 18 h. As in the black bag, the chief reaction products are lead carbonates, oxycarbonate and oxides. Because of the presence of SO_3 in the atmosphere and the use of phosphorus additives in some fuels, small amounts of lead phosphate and lead sulphate are also found.

The sample from the rural area shows clearly that very little lead halide remains. The more insoluble lead salts make up the bulk of the lead particulates.

The results of this study make it unnecessary to postulate photolysis of the lead compounds[5] to account for the loss of halogen. Indeed the results from the black bag in the absence of light make this impossible. The clear parallel between the results from the black bag and the atmosphere strongly suggests that the mechanism is not photolytic.

In the black bag, the primary reaction appears to be a simple acid base reaction with carbonate or hydroxide ion displacing the bromide ion and, in some cases, the chloride ion from the lead halides initially exhausted. Oxidation, however, cannot be ruled out completely.

These results suggest that lead oxide, lead carbonate, basic lead carbonate or a mixture of these would be a good choice for experimental studies of the health effects of lead in the atmosphere.

BIOLOGICAL SCIENCES

Effect of Inclusion of Cellulose in an "Atherogenic" Diet on the Blood Lipids of Children

SUNDARAVALLI *et al.*[1] have reported that increased plasma and liver cholesterol induced by cholesterol feeding in the rat could be largely counteracted by the concurrent feeding of 20% cellulose in the diet. We now report the results of similar investigations on humans.

Ten girls (10–12 yr) who volunteered for the study received (1) control diet (2) control diet with cholesterol (4 g/day) and (3) control diet with cholesterol (4 g/day) and cellulose (100 g/day) in the same order; thus each subject acted as her own control. Each diet was fed for a period of 10 days and the faeces were collected for analysis during the last 3 days. Blood samples were taken at the end of each period, and total and free cholesterol were estimated according to Wootton[2], total lipids by the method of Sperry[3] and phospholipids by the method described by Oser[4].

The composition of the control diet is given in Table 1. The diet provided 1,880 kcalories/day, of which 72% was from carbohydrates, 18% from fat and 10% from protein. Various recipes were prepared from the ingredients shown in Table 1. The cholesterol supplement given during the second and third period was dissolved in the fat by gentle warming and this mixture was used for all the cooking. Cellulose (microcrystalline cellulose, 'Avicel-pH', marketed by FMC Corporation, Marcus Hook, Pennsylvania) given as supplement, formed 20% of the diet; this was mixed with wheat flour–corn starch blend and made into *chapathies* (unleavened bread) which were offered to the subjects. This cellulose is of very fine particle size (>300 mesh) and could be easily incorporated in the diet without affecting the taste and acceptability.

Table 1 Composition of Control Diet

Ingredients of control diet	Daily quantities (g)
Corn starch	150
Wheat flour (80% extraction)	150
Sucrose	40
Groundnut oil	35
Skim milk powder	50
Vegetables	50
Tea leaves	6
Salt	15
Condiments	18

Table 2 Serum Lipids and Faecal Bile Acids of Experimental Children

Diet	Control	Control with cholesterol	Control with cholesterol and cellulose
Cholesterol (mg/100 ml.)			
Total	137.5 (127.1–148.0)	226.3 (184.8–255.1)	170.3 (152.1–190.2)
Free	45.9 (40.3–52.2)	63.1 (51.0–72.1)	44.4 (36.5–57.5)
Total lipids (g/100 ml.)	0.61 (0.56–0.64)	0.81 (0.75–0.84)	0.66 (0.59–0.69)
Phospholipids (mg/100 ml.)	184.9 (170.1–192.1)	244.3 (212.0–266.0)	203.3 (185.3–213.2)
Faecal bile acids (mg/day)	78.5 (71.0–82.8)	146.9 (133.8–162.1)	212.7 (192.1–231.6)

Values for serum lipids and faecal bile acids of the children are given in Table 2. The concentration of serum cholesterol of subjects on the control diet was 137.5 mg/100 ml.; approximately 33% of this was in the free form. Feeding of cholesterol

(4 g/day) resulted in a significant increase in serum cholesterol to 226.3 mg/100 ml. There were concomittantly significant increases in serum lipids and phospholipids. Inclusion of cellulose to the extent of 20% of the diet resulted in a significant reduction in serum cholesterol, total lipids and phospholipids. The faecal excretion of bile acids (mg/day) increased from 78.5 to 146.9 when cholesterol was included in the diet. Inclusion of cellulose in the diet to the extent of 20% increased the bile acid excretion to 212.7.

Keys *et al.*[5] reported that cellulose in the diet did not exert any beneficial effect on lowering of cholesterol. The present studies, however, have shown that cellulose at higher levels (20% of the diet) exerts a beneficial effect in lowering serum cholesterol in children, receiving a hypercholesterolaemic diet. Sundaravalli and Narayana Rao[6] reported that inclusion of microcrystalline cellulose even to the extent of 20% did not significantly influence the utilization of nitrogen in young weanling rats. The paucity of information about the fibre content of human diets makes it difficult to relate the present studies to diets as eaten normally. A study by Hardinge, Chambers *et al.*[7] showed that the fibre intake could vary widely over a period of years without adverse effects on the digestive tract. The amount of cellulose used in these studies is certainly higher than commonly ingested in so called civilized diets.

The mechanism of the effect of cellulose is unknown, but it may result from increased excretion of bile acids in the faeces. Using tagged compounds, Portman and Murphy[8] reported that inclusion of 20% celluflour in a sucrose synthetic diet resulted in an increased excretion of cholate and degradation products of cholate.

We thank Dr H. A. B. Parpia for his interest.

Cytological Evidence for the Association of the Short Arms of the *X* and *Y* Chromosomes in the Human Male

EVIDENCE for the association of the *X* and *Y* chromosomes during the first meiotic division in man has been documented[1,2]. Until the centromere positions of the meiotic chromosomes were located with certainty, no information about the arm relationship between the two sex chromosomes could be obtained. The identification of the positions of the centromere in human male meiotic chromosomes at the late diplotene stage has been reported[3]. This observation revealed that the short arm of the *Y* chromosome was in association with the short arm of the *X* chromosome. Partial support for this finding was presented by Pearson and Bobrow[4], who interpreted fluorescent staining of the distal end of the long arm of the *Y* chromosome of the *XY* bivalent in man as evidence that the short arm of the *Y* chromosome was associated with the *X* chromosome. Because the centromere position of the *X* chromosome could not be demonstrated in their material, it was not possible to determine which arm of the *X* chromosome was associated with the short arm of the *Y* chromosome. The purpose of this communication is to provide additional cytological evidence for the association of the *X* and *Y* chromosomes at their short arms.

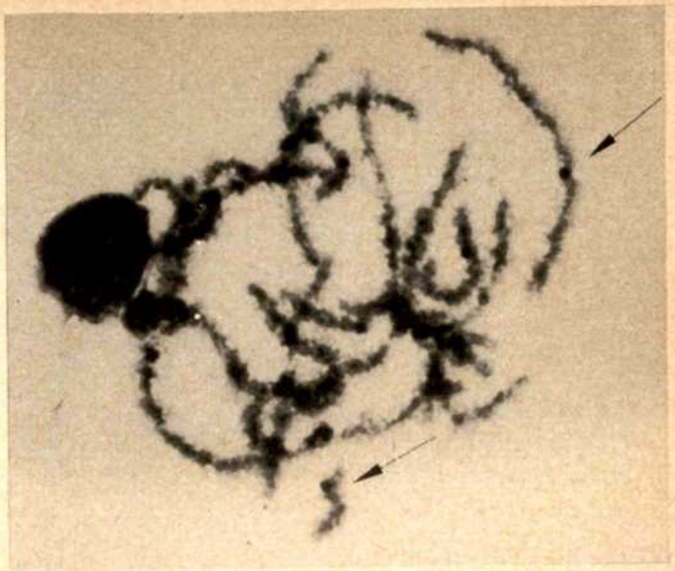

Fig. 1 Cell in pachytene. The broken arrow points to a *G* group bivalent and solid arrow to an *A* group bivalent, most possibly chromosome number 2.

The technique for the preparation of the meiotic material was a modification of that reported previously[5] and was as follows: after the outer membraneous capsule (tunica albuginea) of the tissue was removed, the specimen was teased apart in a Petri dish containing 1% sodium citrate solution by the use of teasing needles. The Petri dish was agitated gently from time to time to loosen the maximum number of cells from the tubules. The cell suspension was decanted into a centrifuge tube and centrifuged at 1,000 r.p.m. for 10 min after which the supernatant was removed and 1 ml. of freshly prepared fixative (3 : 1 methanol and glacial acetic acid) was added in a dropwise fashion. The material was refrigerated at 4° C for 5 min, the cell button was then resuspended in fixative and placed in the refrigerator for a further 25 min. The cells were centrifuged and then washed in a new fixative until a button and a clear supernatant were obtained. The button of cells was then placed on clean slides, flame-dried and stained with Giemsa (Azure Blend Type, Harleco).

The materials used for this report were obtained from the testicular tissue of three men treated for cancer of the prostate. The dark staining bodies which we have taken to indicate the centromere positions were observed not only at the late diplotene stage[3] but also at other stages of meiosis I. For example, some bivalents at pachytene could be readily identified on the basis of length and centromere positions (Fig. 1). It was still technically difficult, however, to identify all the individual bivalents at this stage, because they were elongated and intertwined. Convincing evidence that the dark staining region of the pachytene chromosomes was at the centromere position was presented by Fredga[6] who karyotyped the pachytene chromosomes of the Wallaby kangaroo.

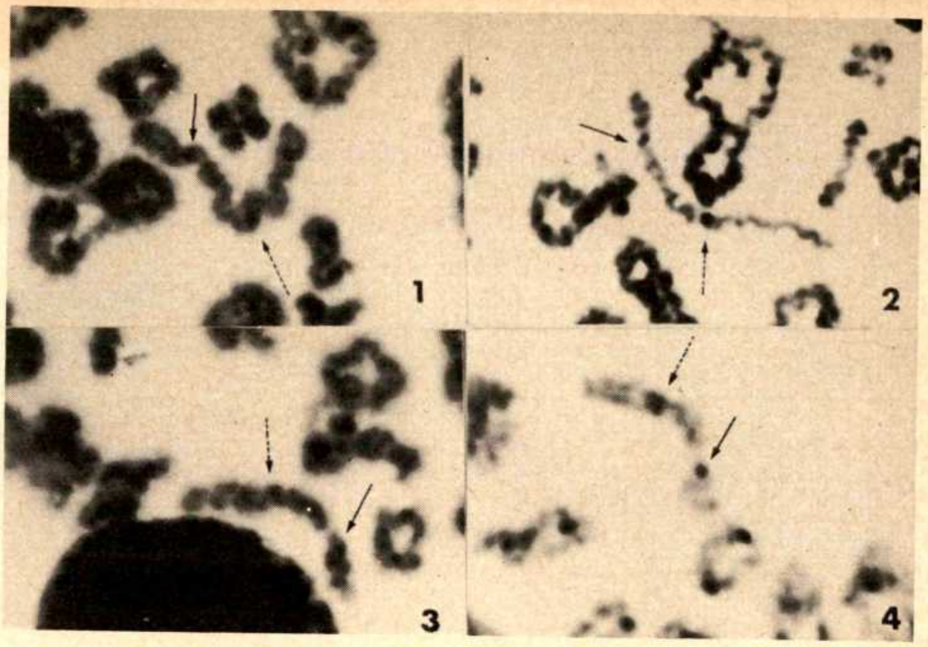

Fig. 2 Partial meiotic chromosome complement from four cells at or near diakinesis. The broken arrow points to the centromere position of the X chromosome and the solid arrow to that of the Y chromosome.

Although the arrangement of the X and Y chromosomes at pachytene could not be visualized because they were condensed into a heteropyknotic sex vesicle[7], they were observed in an end to end relationship at the late diplotene stage as well as at diakinesis. The long and short arms of the two sex chromosomes from ten cells at the latter two stages were measured using camera lucida drawings. The measurements revealed that the mean ratio between the long and short arms of the X chromosomes was 1.37 (s.e. = 0.05) and that of the Y chromosomes 3.57 (s.e. = 0.18). Furthermore, the data confirmed the short arm association of the X and Y chromosomes (Fig. 2).

This study was supported in part by a grant from the Research Corporation. We thank Dr C. E. Ford for helpful comments.

Para-nucleolar Position of the Human Y Chromosome in Interphase Nuclei

INDIVIDUAL human chromosomes cannot be seen during interphase, and little is known of their intra-nuclear position during most of the cell cycle. The principal exception to this has been the X chromosomes: when there is more than one, they condense during interphase to form the sex chromatin, which is often located on the nuclear membrane. It has recently become possible to locate the major portion of the Y chromosome in interphase nuclei[1], and we have used this technique to demonstrate that the Y chromosome is spatially associated with the nucleolus.

Because of their relatively large size and favourable morphology, cultured fibroblast nuclei were fixed in either methanol or Carnoys fixative, stained with quinacrine[1], and viewed on a Leitz ortholux microscope fitted with Ploëm vertical illuminator. The use of incident ultraviolet light and transmitted white light facilitates fluorescent and phase contrast microscopic observations either simultaneously or in rapid succession. A comparison of photographs taken under phase contrast with the same nuclei after Giemsa staining confirmed that the nucleoli could be well defined under phase contrast.

Nuclei in which the Y body could be clearly identified were located, and then examined under phase contrast. Material was obtained from nine individuals of XY sex chromosome constitution, the mean number of cells scored per individual being 133 (range 59–256). The proportion of cells in which the fluorescent Y body was in contact with a nucleolus varied in different individuals from 37%–86%, the overall mean being 59.1%.

Ninety-four randomly selected cells were photographed, and the areas of nuclei and nucleoli measured by planimetry. The mean nucleolar area in different individuals ranged from a minimum of 8.92% (s.d. 3.7) to a maximum of 13.47% (s.d. 4.19) of the nuclear area. The overall mean for ninety-four cells was 10.7%. It is apparent that the proportion of cells in which the Y body lies in contact with a nucleolus considerably exceeds the expectation, had the Y body been randomly positioned within the nucleus. A similar association of the Y body with the nucleolus has also been observed in Sertoli cell nuclei, PHA-stimulated peripheral lymphocytes, and buccal mucosal cells, although phase-contrast observations are much more difficult to make on the latter cell types.

Fibroblast nuclei from a male of XYY sex chromosome constitution showed both Y bodies to be associated with the nucleolus in 36% of cells, while neither Y body was so associated in 24.6%. There was no tendency for both Ys to be associated with the same nucleolus. Nucleolar area was 11.98% (s.d. 2.95) of nuclear area.

In some species the number of nucleoli per nucleus can be related to the number of nucleolar-organizing regions present in the genome[2]. We therefore investigated the relationship of the number of *Y* chromosomes in the karyotype to the mean nucleolar count per cell. The within-individual variability of nucleolar counts made it difficult to get reproducible results on fibroblast nuclei, and this part of the investigation was therefore done on 72 h PHA-stimulated peripheral blood cultures. Preparations were stained with Giemsa, and the number of nucleoli counted in 100 consecutive cells. Two separate counts were made for each individual, and the results expressed as the mean number of nucleoli per nucleus (nucleolar index).

Table 1 Mean Number of Nucleoli per Cell (Nucleolar Index) in Cultured Lymphocytes of Different Chromosome Constitution

Group	Chromosome constitution	No. of individuals	Nucleolar index Mean	s.d.
1	46 *XY*	10	1.86	0.22
2	46 *XX*	10	1.68	0.29
3	47 *XYY*	4	1.77	0.21
4	47 *XXY*	3	1.74	0.16
5	45 *XO*	3	1.69	0.12
6	47 *XXX*	1	1.75	–
7	45 *XYt(DqGq)*	1	1.70	–
8	47 *XX* 13+	1	1.80	–
9	47 *XY* 21+	6	2.12	0.31
10	47 *XX* 21+	5	2.26	0.31

Data on forty-four individuals of different chromosome constitutions are summarized in Table 1. Analysis of variance on the whole data, and comparisons of group means with one another by *t* tests, demonstrated no significant effect of sex chromosome complement on the nucleolar index. Individuals with trisomy 21 had a significantly raised nucleolar index ($P<0.001$ for both sexes combined). The numbers available for examination in some of the groups, however, are so small that real differences could have gone undetected.

Information on the nucleolus-organizing capacity of human chromosomes is based largely on the study of "satellite associations" persisting into metaphase. Although the *Y* chromosome long arm does have a secondary constriction[3], and there have been suggestions that it may be involved in satellite association[4], the weight of evidence seems to be against this view[5]. Our demonstration of a spatial proximity of this chromosome to the nucleolus does not necessarily imply a functional relationship, but several features of the *Y* chromosome may be relevant to this question. (*a*) Intense quinacrine fluorescence is characteristically seen, apart from the *Y* long arm, on the short arms of the acrocentric *D* and *G* group chromosomes and next to the centromere of chromosome 3. The *D* and *G* group short arms are the known nucleolus-organizing regions of the human genome[6], and we have observed interphase fluorescence from a marker chromosome of this group associated with the nucleolus in a large proportion of nuclei. Whether the centromeric region of chromosome 3 is also related to the nucleolus is not yet known. (*b*) Recent techniques for demonstrating a form of constitutive heterochromatin stain the distal part of the *Y* long arms[7]. The procedure involves denaturing and reannealing DNA, and is thought to demonstrate highly repetitive DNA sequences. There is evidence that nucleolus-organizing regions consist of repetitive DNA[8]. (*c*) The intensely fluorescent part of the *Y* chromosome is known to vary considerably in size, and may even be completely absent, without apparent clinical effect[9,10]. This is compatible with the concept that it is composed of genetic sequences also present elsewhere in the genome. (*d*) The only well proven function of the *Y* is in sex determination, and these genes are probably localized in the non-fluorescent area[11]. (*e*) The human *Y* chromosome is relatively large compared with those of other primates, which lack intensely fluorescent chromatin[12]. This again suggests a genetic content over and above that necessary for male sex determination.

These arguments are all indirect, but it seems possible that the distal part of the long arm of the *Y* chromosome contains a specialized form of genetic material related to nucleolar function. Further investigation may throw light, not only on the function of the *Y* chromosome, but on the nature of the histochemical differentiation recently revealed within the human chromosome complement.

Evidence for a Genetic Factor in the Transmission of Spontaneous Lymphosarcoma (Leukaemia) of Young Pigs

A histological survey of lymphosarcoma[1] (leukaemia) in 1968 in abattoirs throughout Great Britain showed an incidence of twenty-five cases per million pigs slaughtered, that is, ninety-two cases from 3.7 million pigs. There was multicentric lymphosarcoma in fifty-seven pigs and thymic lymphosarcoma in thirty-five pigs, and there was no indication of lymphosarcoma in other pigs on the farms concerned or even that it had occurred there previously. It is therefore of some interest that we have now found lymphosarcoma to have occurred several times in a single herd.

A minimal disease (MD) piggery established in 1963 was stocked with colostrum-deprived hand reared Large White piglets obtained by caesarian section from nine unrelated sows. The herd has since been maintained as a closed community with fourteen to seventeen breeding sows and one or two boars. The only contact with other pigs has been the occasional use of semen from outside boars for artificial insemination.

In August 1966, lymphosarcoma was diagnosed in two 3 month old sibling piglets. These were the offspring of a boar (D) mated to his sister (362). The boar died before the mating could be repeated but the sister subsequently had litters of nine and four offspring respectively to another brother (138). None of these developed lymphosarcoma although four were kept for more than a year. No further cases were detected in the herd until September 1969, since when nineteen have occurred, all confirmed at necropsy as multicentric lymphosarcoma. Although present in many of these pigs, the thymus was not involved in the disease.

The age at which the disease could first be diagnosed with any certainty conformed to a more or less normal distribution between 6 and 18 weeks, apart from one case in which diagnosis was obscured for several weeks by intercurrent disease.

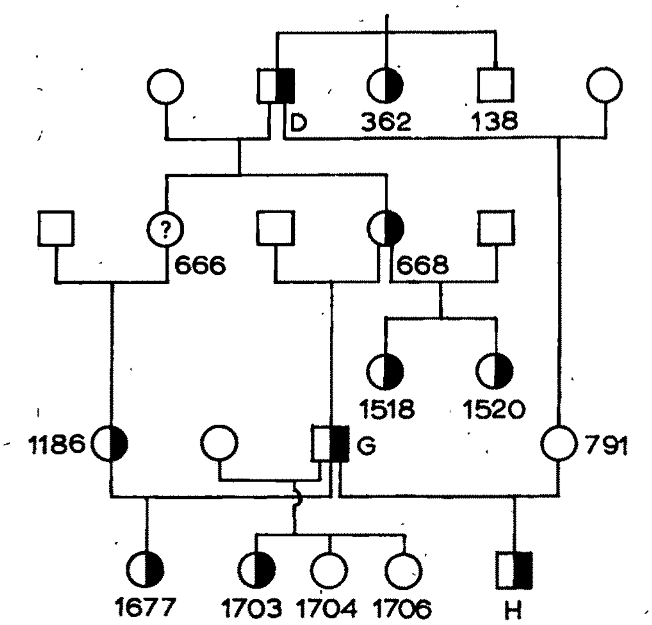

Fig. 1 Relationship between parents of lymphosarcoma cases; Square, male; circle, female; half filled symbol, parent of L/S; open symbol, not parent of L/S; ?, status doubtful, not suitably test-mated.

Most animals reared in the piggery are slaughtered for bacon at 5–6 months of age but to date eighty-two animals have been kept for breeding, most for 2 or 3 yr, some for 6 or 7 yr. No signs of lymphosarcoma have been detected in any of these which include all the parents of all known lymphosarcoma cases. The entity we are reporting is thus essentially a disease of young pigs. Occasionally we have found lymphosarcoma in older pigs in other herds but such cases are sporadic. This is in keeping with other reports[1,3–5].

Eleven of our cases were males (including five castrates) and ten were females. All resulted from matings with a degree of consanguinity of four or less between three boars and seven sows which had a common ancestry. The ways in which they were mated and the distribution of lymphosarcoma cases in the resultant litters are detailed in Table 1.

Table 1 Matings Producing Lymphosarcoma and Distribution of Cases among Litters

Matings			Composition of litters		
			No lymphosarcoma		
Boar	Sow	Degree of consanguinity	Died before 6 weeks	At bacon weight (5–6 months)	L/S cases
D	362	2	2	7	2
G	668	1	3	7	1
			7	3	2
	1,186	4	1	9	1
			2	8	0
			6	6	2
	1,518	2	1	5	1
			1	9	1
	1,520	2	5	4	2
			4	9	2
	1,677	1	4	0	2
H	1,703	2	2	5	5

A number of piglets died before 6 weeks of age and are not included in our assessment of incidence of lymphosarcoma. This averaged 22.6% which is not significantly different from the 25% to be anticipated if an autosomal recessive gene were involved ($\chi^2 = 0.03$, 1 d.f.). This hypothesis is supported by the facts that when any of the ten parents of lymphosarcoma cases was mated to other pigs no cases were found among 478 offspring in fifty-seven litters, nor were any cases encountered in 753 offspring in ninety-nine litters arising from matings which excluded the ten, even though in both groups about a quarter of the matings had a degree of consanguinity of four or less. A proportion of animals in the affected strain would be expected to be non-carriers of the disease. We have found four such animals (138, 791, 1,704, and 1,706). It has so far not proved possible to use affected animals in test matings which might help to confirm the hypothesis because they have all remained stunted and sexually immature even when living to be more than 1 yr old.

Evidence from Russia[6] suggests that in cattle susceptibility to the disease is inherited through a recessive homozygous factor but the situation differs from ours in that the disease in cattle tends to appear later in life when they have already bred successfully and in the Russian herd every affected offspring had an affected or suspect parent.

We thank Professor Sir Alexander Robertson for encouragement and facilities.

Cell Division in Medium lacking Serum Growth Factor: Comparison of Lines transformed by Different Agents

Cells of the permanent lines derived from mouse embryo tissue, 3T3 and Balb/c 3T3, exhibit density dependent inhibition of cell division[1,2] anchorage dependence[3,4], and also require a factor in serum to initiate DNA synthesis[5–8], but these growth controls[4,6,9–11] are lost in transformed cells. It has been suggested that loss of density dependent inhibition is a consequence of the loss of a requirement for serum factor[6], in which case it would be expected that transformed lines derived from 3T3 would lack both growth controls. We have therefore tested various transformed lines of Balb/c 3T3 lacking the density dependent inhibition for the ability to grow without this serum factor or factors. Both virus-transformed lines of Balb/c 3T3 and independent isolates of Balb/c 3T12 (see ref. 2) grow well in medium lacking the serum growth factor(s), but most non-virus-transformed variants of Balb/c 3T3 grew poorly if at all. These observations suggest that the loss of density dependent inhibition of growth does not necessarily depend on the loss of the need for serum growth factor.

Balb/c 3T3, clone A31, was separately transformed by the small plaque mutant of SV40, the Kirstein and Moloney strains of murine sarcoma virus (MSV) and the Bratislava strain of Rous sarcoma virus (RSV). Most of the other transformed clones were isolated from the occasional cells that spontaneously grew out of the Balb/c 3T3 monolayer. We also used one transformed line induced by X-irradiation (1,500 rads) and another induced by ultraviolet light (2,000 ergs mm^{-2}). All the transformed lines had saturation densities ranging from 3.5–7 × 10^5 cells cm^2. The preparation of factor-free medium which permits growth of SV40-transformed Balb/c 3T3 but not of normal cells has been described[12].

Exponentially growing cultures were trypsinized and planted in factor-free medium and medium containing 10% whole calf serum (complete medium) at cell concentrations ranging from 100–6,000 cells per 50 mm Petri dish (Falcon). After 2–3 weeks the plates were fixed, stained[12] and the colonies scored. In case the lines did not grow in factor-free medium because they were unable to settle onto the plastic dish, all lines with little or no growth were also planted in complete medium and changed to factor-free medium 1 day later.

Fig. 1 gives the relative plating efficiencies of cells in factor-free medium (colonies growing in factor-free medium × 100/colonies growing in complete medium). All SV40-transformed clonal lines had efficiencies, in factor-free medium, of 20% to 60%, as did clonal lines transformed by sarcoma virus. The latter included a line transformed by the Moloney strain of MSV with associated leukaemia virus (G), two lines without associated leukaemia virus (one transformed by Moloney MSV (*H*) and one by Kirstein MSV (*I*)[13]) and one line transformed by RSV (*J*) without associated leukaemia virus. All the Balb 3T12 lines had high relative plating efficiencies in factor-free medium, and included a line (*N*) infected with murine leukaemia virus and three (*K*, *L*, *M*) with no demonstrable leukaemia virus[14]. In these conditions, the plating efficiency of Balb/c 3T3 was $<0.1\%$ (data not shown).

The virus-transformed and non-virus-transformed Balb/c 3T3 lines differed in their ability to grow in factor-free medium. Only three-eighths of the non-virus-transformants grew well; the remainder grew poorly, if at all. There was no correlation between the saturation densities of these lines (which ranged from $3.5\text{–}6.5 \times 10^5$ cells cm^{-2}) and their ability to grow in the absence of serum growth factor(s). Planting cells directly into factor-free medium, or shifting cells from complete to factor-free medium, gave similar relative plating efficiencies for all the lines except (*P*) which had an efficiency of only 1% after the cells were planted directly in factor-free medium although it increased to 125% after being planted first in complete medium. This line may require a serum factor lacking in factor-free medium to settle and flatten out[15].

Our experiments confirm and extend the observation that all virus-transformed lines of Balb/c 3T3, as well as Balb/c 3T12, can grow in medium depleted of the serum growth factor(s). Furthermore, because most non-virus-transformed cells grow poorly, if at all, it is clear that loss of density dependent inhibition does not always result from a lowered requirement for these factors.

In virus transformations, there are two indications that loss of density dependent inhibition is not identical to decreased requirement for serum growth factor(s). First, the two properties are acquired at different times after SV40 infection: immediately after infection, Balb/c 3T3 cells become able to grow in factor-free medium[12] although several generations are necessary before the cells lose density dependent inhibition[16]. Second, there are SV40-transformed lines which have only one of the growth properties associated with virus-transformation, that is, the ability to grow in factor-free medium. Most of these lines may be the result of a secondary alteration as they were selected from a fully transformed line by FUdR[17], but because there was no secondary selection involved in the development of two lines with these properties (ref. 13 and our unpublished observation) it is likely that the virus induced only the ability to grow in factor-free medium.

The simplest hypothesis consistant with all the data is that the two growth properties, that is loss of density dependent inhibition and loss of requirement for serum factor, are independent changes and that viruses usually induce both. Alternatively, there may be more than one way for a cell to lose density dependent inhibition. In virus-transformed lines and possibly in those non-virus-transformed lines that also grow in factor-free medium, the loss of requirement for serum factor may be necessary, but not sufficient, for the loss of density dependent inhibition. In other cases (that is most non-virus-transformed lines) a mechanism not dependent on the loss of serum factor requirement could also cause the loss of density dependent inhibition. Whichever hypothesis is correct, it is clear that these two growth properties are not identical.

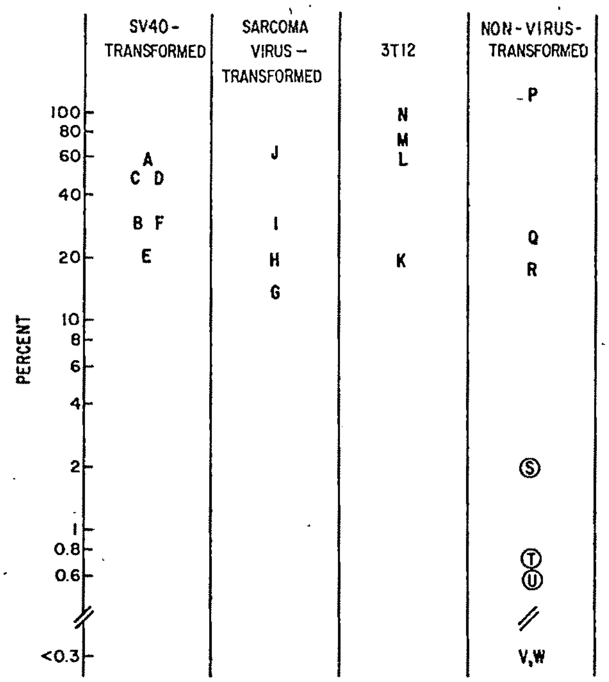

Fig. 1 Relative plating efficiency of transformed lines in medium lacking serum growth factors. Data are expressed as colonies growing in factor-free medium ×100/colonies growing in complete medium. Colonies were scored 2 weeks after planting. The circled letters indicate colonies that grew more slowly in factor-free medium and were scored, 3–4 weeks after planting. SV40-transformed lines: *A*, SV$_1$; *B*, SV$_3$; *C*, SV$_4$; *D*, SV$_5$; *E*, SV$_6$; *F*, SVT$_2$. Sarcoma virus transformed lines: *G*, MS24; *H*, 85–2; *I*, KA31CL$_{234}$; *J*, B77. Balb/c 3T12 lines: *K*, 3T12/1; *L*, 3T12/2; *N*, 3T12/3; *N*, 3T12/P13. Non-virus transformed lines: *P*, IIC12; *Q*, R-4; *R*, TA31; *S*, εA31; *T*, A31A1C11; *U*, 17C11; *V*, STA31, *W*, IC16.

We thank Dr S. Aaronson for many transformed lines, Miss K. Reynolds and Mrs K. Gottesman for technical assistance, and Dr G. Todaro for discussions and the hospitality of his laboratory. This work was supported by a contract from the National Cancer Institute.

Incidence of Mycoplasma Infection in Guinea-pigs

THE isolation of a new mycoplasma species, *Mycoplasma caviae*, was recorded recently[1]. This species has been isolated from the nasopharynx and vagina of 10% of 232 guinea-pigs and is apparently non-pathogenic to these and other common laboratory animals. During this survey, no other known species of mycoplasma were isolated. (A strain of *M. caviae* G. 122 has been lodged in the National Collection of Type Cultures and has been given the reference number NC/TC 10126.)

Although we have failed to isolate other known species of mycoplasma from 232 guinea-pigs, it has been claimed that in Germany all guinea-pigs carry *M. pulmonis* in the vagina[2]. It is interesting to speculate why the incidence of infection in Germany should be so different to that in the United Kingdom. Further information on the incidence of mycoplasma infection of guinea-pigs in different countries would be most interesting.

Transplacental Transmission of Endogenous Interferon in Pregnant Mice inoculated with Influenza or Newcastle Disease Viruses

THE possibility of intrauterine infection transmitted from affected mother to foetus has been established by both clinical[7,11] and experimental[3,6,9,10] investigations. Inoculation of pregnant animals with pathogenic viruses often brings about foetal infection resulting in impaired intrauterine development. When non-pathogenic strains are used, however, pregnancy may proceed normally and result in the birth of healthy offspring[4]. It has been demonstrated repeatedly that viruses with low pathogenicity for animals are effective producers of endogenous interferon. Preliminary administration of such interferon inducers has been shown to promote non-specific protection in animals against inoculation of lethal viruses[5,8].

In our investigation we used influenza A1/3711 virus and Newcastle disease virus (NDV) which were non-pathogenic for mice for interferon induction. These viruses are known to stimulate active production of endogenous interferon in mice, resulting in development of short term insusceptibility to subsequent inoculation with lethal influenza infection[2]. The aim of our study was to test the possibility of transplacental transmission of endogenous interferon from mother to foetus with resulting activation in the offspring of non-specific immunity to infection with various viruses.

Production of endogenous interferon was induced on days 17–21 of pregnancy by intranasal instillation of 0.2 ml. of allantoic fluid containing influenza A1/3711 virus, or by intravenous administration of 1.0 ml. of NDV. Both preparations contained 10^6ID$_{50}$/0.2 ml.

At different intervals after A1/3711 or NDV inoculation, sera and suspensions of washed lung, placenta and foetal tissues were tested for virus and interferon content. Serum and lungs of newborn mice were tested for the same. Interferon was titrated on mouse fibroblast tissue cultures in terms of suppression of cytopathogenic action of vesicular stomatitis virus. Influenza A1 virus or NDV were inactivated in these specimens by preliminary treatment in acid medium (*p*H 2.0).

Newborn mice from experimental or control (uninoculated) mothers were challenged on different postnatal days intranasally (0.06 ml.) with mouse-pathogenic allantoic influenza AO/PR8 virus of 10^4ID$_{50}$/0.2 ml. activity. The inoculated sucklings were observed for 1 month.

Inoculation of influenza A1/3711 virus or NDV 3–4 days before birth did not affect the course of pregnancy, and the offspring survived the observation period.

Intranasal inoculation of pregnant mice with influenza A1 virus resulted in subclinical infection, accompanied by significant accumulation of interferon in the lungs from the first day after inoculation. Maximal values of interferon activity were obtained on days 3–4, when the level in the lungs was two to four times higher than that in bloodstream, uterus, placenta or foetuses (Table 1).

Table 1 Interferon Levels in Serum and Organs of Mice inoculated with Influenza A1/3711 or Newcastle Disease Viruses on Days 17–18 of Pregnancy

Interferon induced with virus	Specimens tested	Time of interferon titration (h after inoculation)				
		6–8	24	48	72	96
Influenza A1/3711	Serum*	—	2	8	32	16
	Lungs†	—	4	8	64	64
	Uterus	—	2	4	8	4

Newcastle disease	Serum	512	128	32	16	4
	Uterus	64	16	4	—	—
	Placenta	64	32	4	2	—
	Foetus	64	24	4	2	—

* Activity of interferon in U/ml. of undiluted serum.
† Activity of interferon was tested in 50% suspension of washed organs and then was calculated on wet weight.

In contrast to influenza virus, NDV induced production of maximal interferon levels in circulating blood as early as 6–8 h after inoculation. At this time, high levels were found in uterus, placenta and foetuses (64 U/ml.).

The results of this investigation demonstrate the possibility of antenatal (intrauterine) transmission of non-specific resistance from mother to foetus. A positive correlation was found between intensity of interferon production in pregnant mice by term and the grade of resistance of their offsprings against lethal influenza infection. Mice born of experimental mothers were fully protected against fatal doses of influenza AO virus if the time of birth corresponded to peak interferon production in the mother. When birth occurred during a period of minimal interferon production in the mother, the extent to which the offspring were protected against influenza AO/PR8 virus decreased considerably (Table 2).

Influenza virus AO/PR8 was 100% fatal in the offspring of uninoculated (control) mice, at any postnatal age. But the offspring of females subjected to interferon induction during pregnancy and challenged on the first, third or fifth days after birth with the same fatal doses of influenza AO virus, survived the whole observation period. Complete protection of off-

* Compared with groups of control sucklings in which influenza AO virus caused 100% death, at any age after birth.

spring was demonstrated in animals born at the time of peak interferon production induced in mothers with A1/3711 virus or NDV.

When older sucklings (7–13 days after birth) were challenged, their protection against influenza virus AO/PR8 was found to have diminished, but still persisted at the 50–70% level, while death was delayed (for 3–4 days), compared with control sucklings.

Protection of newborn mice may be effected by relatively low concentrations of interferon, which cannot be detected by current methods of titration. This is confirmed by the results of titration of influenza AO/PR8 virus on the 3 day old offspring of mothers in whom interferon had been induced with NDV 1 day before term. Animals which received maternal interferon before birth proved to be fully resistant to AO virus. Interferon circulating in their bloodstream (1 : 2 titre) neutralized 10^5 infective doses of the challenging virus (Table 3). This is supported by tissue culture experiments[1].

Table 3 Titration of Influenza AO/PR8 Virus on 3 Day Old Offspring of Mice exposed to Interferon Induction with Newcastle Disease Virus inoculated on Days 18–19 of Pregnancy

Groups of sucklings	Challenged with dilutions of influenza AO/PR8 virus						
	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}
Born of mothers exposed to interferon induction	18	17	14	10	8	6	
Died when resistance challenged	7	2	0	0	0	0	
Death rate (%)	39.0	12.0	0	0	0	0	
Born of control mothers	4	8	7	9	14	13	6
Died	4	8	7	9	10	4	0
Death rate (%)	100	100	100	100	71.0	31.0	0

These studies confirm the possibility of protecting mice antenatally against postnatal fatal influenza infection. Here, the leading part belongs to endogenous interferon, which penetrates the placenta and creates in the foetus a state of resistance against virus infection. The significance of maternal interferon in protection of newborn mice is supported by experiments in which normal newborn sucklings were inoculated with influenza A1/3711 virus at different postnatal days. No interferon could be detected in the lungs of mice inoculated within the fifth to seventh postnatal days. With age, however, the production of interferon increased.

Genetic Recombination in Malaria Parasites

THE complexity of the life cycle of malaria parasites and the lack of suitable strain characters which could be used as genetic markers have made genetic studies of these organisms difficult. We have now available, however, a number of strains of *Plasmodium berghei* isolated from wild rodents and mosquitoes in Africa, which can be differentiated from one another by starch-gel electrophoresis of certain enzymes[1]. We have also derived parasite lines resistant to the drug pyrimethamine from some of these strains, and such resistant lines remain stable even in the absence of the drug. By making crosses between lines which differ in both enzyme type and drug sensitivity, we have been able to obtain parasites exhibiting recombinant characters.

The parasite lines selected for use are described here as lines A and C. Line A was derived from strain 17X of *P.b. yoelii* and is pyrimethamine resistant. The resistance was produced in a single step[2] by treating mice infected with strain 17X with pyrimethamine at doses of 50 mg/kg daily for 4 days. Line A, like strain 17X, contains the electrophoretic form of the enzyme glucose phosphate isomerase denoted GPI-1[1]. Line C was derived from strain 33X of *P.b. yoelii*, and is pyrimethamine-sensitive. In the 4 day suppressive test[3], it is more than fifty times as sensitive to pyrimethamine as line A. Line C contains the enzyme form GPI-2[1].

The sequence in which this work was conducted is presented in Fig. 1. Equal amounts of blood (0.3 ml.) were taken from two tree rats (*Grammomys surdaster*), one of which was infected with line A and the other with line C. The blood from each animal was mixed and injected intravenously into an uninfected tree rat. This produced an immediate patent parasitaemia in the recipient (113 A+C in Fig. 1). Mosquitoes (*Anopheles stephensi*) were fed immediately on this animal in the hope that gametes of each strain would mix. The resulting sporozoites were used to infect further tree rats from which ten C57 black mice (127 A+C in Fig. 1) were subsequently infected. Five of these mice were treated with subcutaneous doses of pyrimethamine[4] at 15 mg/kg daily for 4 days. All ten mice became infected and examination of the parasites on starch gels (Fig. 2) revealed the presence of both GPI-1 and GPI-2 in all animals.

To confirm that the GPI-2 parasites in the treated mice were drug-resistant, infected blood from these mice was diluted in serum Ringer[5] into aliquots containing an average of one parasitized cell. The aliquots were inoculated into individual mice, from which blood infections were established. Two GPI-1 and two GPI-2 lines were derived in this way, each of which was found to grow equally well when subjected to pyrimethamine treatment.

As controls the parent lines A and C were passaged through mosquitoes, tree rats and mice in the same way as the mixture. Line A parasites survived drug treatment, and line C parasites were eradicated. The work has been repeated several times with similar results; line C has been exposed to pyrimethamine at doses of 15 mg/kg in fifty mice, none of which has remained infected. We think it very unlikely, therefore, that mutation could account for the appearance of resistant GPI-2 parasites in the mixed infections.

Two further controls were set up to determine whether the recombinant parasites obtained were due to the phenomenon described by Yoeli *et al.*[4] as "synpholia". In synpholia, it is suggested that pyrimethamine resistance can be transferred from one strain to another when they grow up together in blood cells of the same host. In the first control, tree rat 113A+C (inoculated with equal numbers of blood parasites of each line) was kept alive for 7 days after mosquitoes had fed on it. Blood parasites from this animal were then used to infect ten mice, five of which were treated with pyrimethamine. In these mice, only GPI-1 parasites survived, but in the untreated mice both GPI-1 and GPI-2 parasites were present. In the second control, sporozoites of each parent line were pooled and inoculated into tree rats. After five days, blood parasites from these animals were used to infect ten mice, five of which were given pyrimethamine. In untreated animals, both GPI-1 and GPI-2 parasites were detected, while the animals given pyrimethamine contained only GPI-1 parasites after treatment.

We have been unable, therefore, to produce parasites exhibiting recombinant characters by simply mixing blood parasites or sporozoites of the parent lines. This does not disprove the phenomenon of synpholia, which may occur as a rare event detectable only when double selection pressure is applied[4], but suggests that it cannot account for our results.

We consider that these results are important in two respects. First, they show that a conventional genetic analysis of malaria parasites is possible. This should enable us to obtain much more precise information than has been available hitherto on the biological basis of such important characters as drug resistance and virulence. Second, they indicate that genetic recombination is continually taking place in natural populations of malaria parasites, which enables the rapid evolution of new strains and their spread in populations of animals and man. We propose to exploit the technique outlined here to investigate the nature of other types of drug resistance as well as enzyme polymorphism and virulence.

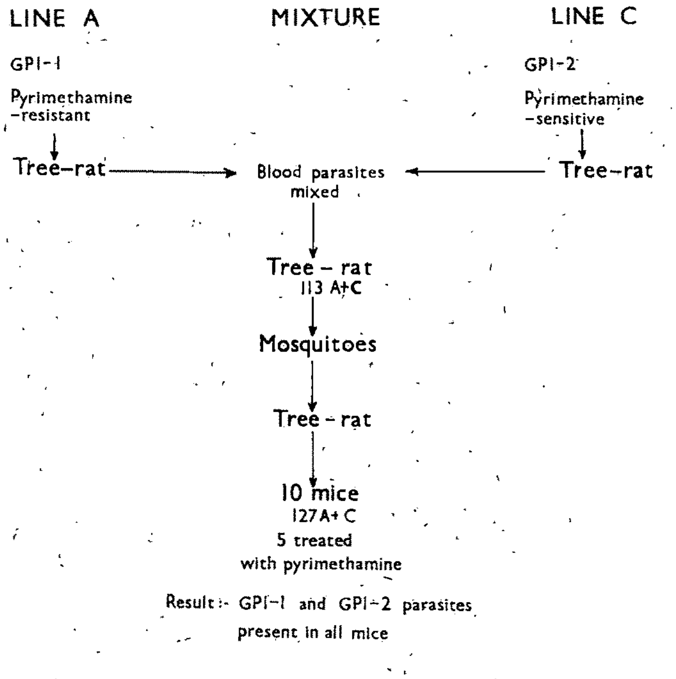

Fig. 1 Procedure adopted in producing recombinant parasites.

Frequency Analysis of the Thirst Control System

DRINKING is essential for the homeostasis of body fluids, and a theoretical structure which makes the principles and details of homeostasis explicit is provided by control theory. A control model of thirst has been described by Oatley[1,2] and simulated on a digital computer[3].

Responses to sinusoidally varying stimuli can give quantitative information about the structure of biological control systems[4,5], and we present here an analysis of drinking by rats in response to sinusoidal salt injections and compare it with the simulated drinking response of the model[3]. We show how frequency analysis applied to a system which has non-linear components (for example, a threshold), can indicate the relative importance of linear and non-linear components.

Sinusoidal infusions of sodium chloride were given at frequencies of 1, 2, 4 and 8 cycles per hour (c.p.h.) to sixteen albino rats chronically implanted with jugular cannulae made of silicone rubber tubing. The mean body weight of the rats was 387 g, and this value was also used for the simulation. The injection waveform was controlled by pulsing an infusion pump at intervals varying sinusoidally with time. The flow rate of hypertonic salt solution into the rat produced in this way approximated the equation:

$$A + A\cos\omega t \qquad (1)$$

where A is the mean rate, 0.0544 mequiv. of Na/min. The infusion varied between zero and $2A$ mequiv./min. The concentration of the salt was 3 M, and injections were continued until a sufficient number of cycles (a minimum of 4 at 1 c.p.h. and a maximum of 24 at 8 c.p.h.) had been accomplished. All rats drank water in response to at least one infusion frequency (each rat had one frequency per day) but clotting of cannulae sometimes occurred so that some rats had to be discarded. They were also relieved of further duty if signs of discomfort appeared during injection. Although we collected between eight and ten readings at each frequency, only three of the rats ran satisfactorily through all four.

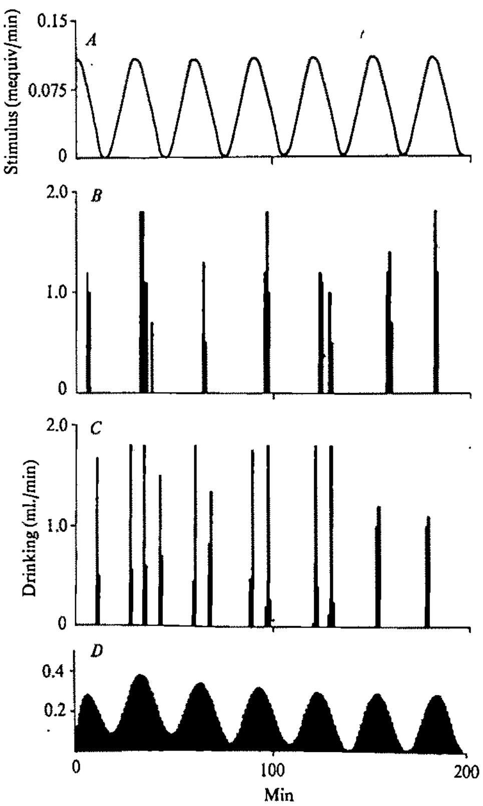

Fig. 1 Sinusoidal input infusion at 2 c.p.h., and histograms of drinking responses to it: (*A*) input infusion defined by equation (1); (*B*) typical experimental result showing one rat's drinking response; (*C*) computer simulation response run with threshold; (*D*) computer simulation response run without threshold. The histograms (*B*, *C* and *D*) represent drinking rate, with the height of each vertical bar showing the volume of water drunk in each 1 min period of the 200 min test. Note that the vertical scale for histogram (*D*) is exactly twice that of histograms (*B* and *C*).

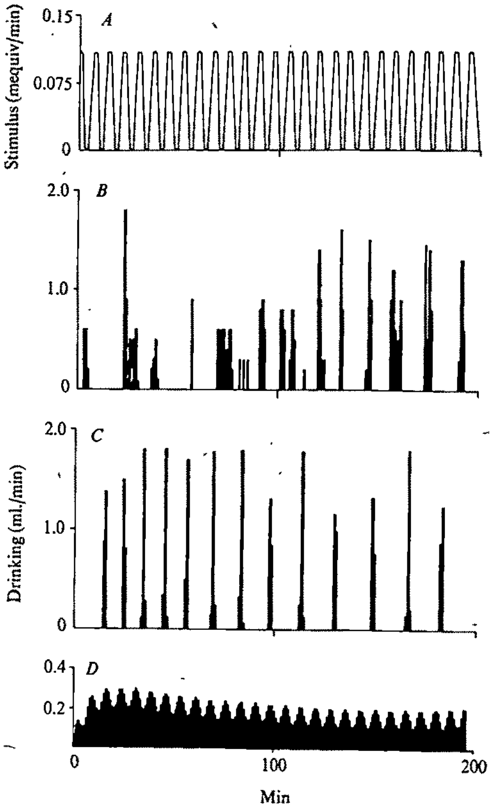

Fig. 2 Sinusoidal input infusion at 8 c.p.h. and histograms of drinking responses to it. Except for the higher frequency the description is as for Fig. 1.

Fig. 1*b* shows a typical response to a 2 c.p.h. stimulus, and Fig. 1*c* shows the computer simulation of this experiment. At 1 and 2 c.p.h., responses consistently showed the same dominant frequency as the input stimulus. In the 4 and 8 c.p.h. results, the pseudo-linear following of the input frequency that occurred at the lower frequencies failed to occur. Instead of transmitting the 4 and 8 c.p.h. signals, animals and simulation responded by an oscillation of drinking at a lower frequency (Fig. 2).

The principal non-linear component in the system is a threshold, which the deficit of body water must reach for drinking to be initiated. Toates and Oatley[3] reviewed experiments in which the value of the threshold has been measured, and took 0.7 ml./100 g body weight as a typical value, which also fitted experiments reported in that article, as well as the data reported here. When the threshold was removed from the simulation, the computer followed input frequencies throughout the range tested, that is, 0.16 to 30 c.p.h. This response, without the threshold, was totally different from that of rats or of the complete simulation (Figs. 1*d* and 2*d*).

Frequency response methods are most useful for linear systems, but an output from non-linear systems can be approximated by a sinusoid at the input frequency and of an appropriate amplitude and phase. A computer program was written to perform the fitting procedure. It searched each combination of amplitude and phase to find the best sinusoidal fit to the drinking data, using as a criterion the minimum value of the square of the error at each point summed over the time observed. Functions were fitted after discarding the first 30 min of the drinking response, to exclude the major part of transient effects.

The open circles in Fig. 3 show the gain and phase of the sinusoids that best fitted the response of the model without the threshold, measured at several frequencies. This response approached a maximum phase shift of −90°, characteristic of a

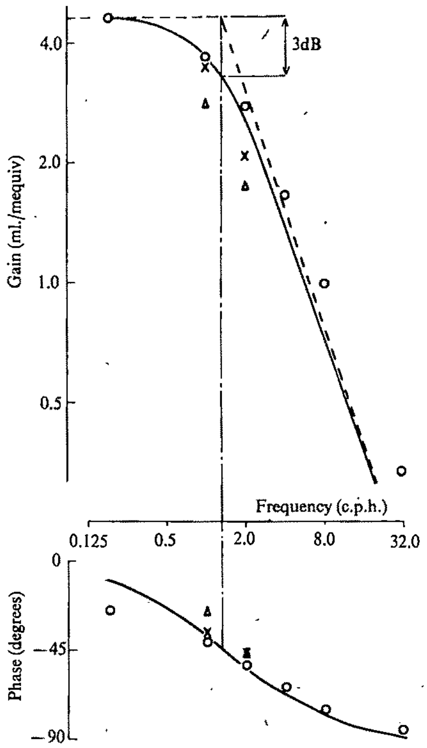

Fig. 3 Gain (expressed as drinking rate in ml./min, divided by input infusion rate in mequiv. of Na/min) and phase plots of frequency responses. The solid lines represent the function $K/1+\tau s$, with $\tau=0.12$ h, the lines - - - are the low and high frequency asymptotes to this function, and the line —.— indicates their intersection at a frequency equal to $1/2\pi\tau$. Best fitting sinusoidal frequencies for experimental data and computer runs are shown by: (△) mean experimental results: (×) computer simulation, with threshold; (○) computer simulation without threshold.

first order system described by the transfer function

$$H(s) = \frac{K}{1+\tau s} \qquad (2)$$

where K is the gain constant, τ the time constant, and s the Laplace operator.

McFarland and Budgell[6] found a transfer function for key pecking by thirsty birds in response to modulations of ambient temperature which was of the same kind as this drinking response to salt injections, though it had a slightly smaller time constant.

The phase lag of a first order system is given by: arctan $\tau\omega$, where ω is the radian frequency per unit time. The mean value of τ calculated from the phase results of the simulation without the threshold was 0.12 h (7.2 min) and with this value, the gain and phase given by equation (2) are shown as solid lines in Fig. 3.

Though the simulation contains non-linearities other than the threshold, Fig. 3 shows the gain of the simulation without threshold to be well fitted by this first order characteristic; and the phase also, except at the lowest frequencies. The best fitting sinusoidal responses for the experimental results and for the simulation with threshold at 1 and 2 c.p.h. are also plotted on Fig. 3 and both gain and phase approach that of the first order approximation. Since frequency following was abolished at 4 and 8 c.p.h. no points could be plotted for these frequencies.

An overall transfer function such as equation (2), can give some idea of the basic structure of a biological system. In this case the first order function arises because rates of flow into and out of body fluid compartments (hypertonic saline causes flow of water out of the cellular compartment) are integrated, and drinking acts as a feedback signal, restoring deficits. An integrator with feedback around it constitutes just such a first order system as described by equation (2), but frequency analysis applied to the real system and to the model[3] indicates that characterization of the system as first order with $\tau=0.12$ h is only a superficial description of the system. It gives no clue as to how physiological processes make up the total system. In comparison with the three components (summing junction, integrator and constant coefficient) required to represent the first order transfer function (2), the block diagram of our simulation[3] which contains a minimal representation of the physiological events that control thirst and body water, has eighty-seven such elements. Clearly there are limits to the adequacy with which transfer functions derived from overall linear frequency analysis can represent what is going on in biological control systems.

In this analysis, however, frequency methods have first confirmed the adequacy of the model[3] (built on a physiological understanding of the component processes and with no arbitrary components or *ad hoc* alteration of parameters) to represent the real system and to generate an overall drinking response comparable with that of a real animal; and, second, these methods establish the relative importance of linear and non-linear features of the system. The time constant (0.12 h) of the system estimated from this small signal analysis differs from the estimate of 0.5 h, in response to a single large transient injection of 2.73 mequiv. of sodium[3]. Thus even the pseudo-linear behaviour at lower frequencies provides evidence for non-linearity, which for large signals is due to non-linear inhibition of drinking by large volumes of water in the stomach.

The claim by Corbit[6] that there is no threshold for drinking in response to hypertonic NaCl seems to be refuted, for in these experiments the threshold dominated the form of the response. Apart from making drinking intermittent at all frequencies (see Figs. 1 and 2, *b* and *c*) a threshold with hysteresis[3] was able to account for the fact that drinking of neither the model nor the rat was able to follow the input at higher frequencies. At 4 and 8 c.p.h. the integral of the rate of salt injected in any one cycle was not sufficient to exceed the threshold. Instead drinking in response to these frequencies was similar to that for a steady infusion at the same mean rate; it exhibited a relaxation oscillation as a function of the mean infusion rate and the threshold value. For the simulation with the threshold the frequency of the relaxation oscillation was approximately 3.5 c.p.h. (Fig. 2). Thus, although with infusions of 1 and 2 c.p.h. no rat ever missed drinking in response to any cycle of the input, at 4 and 8 c.p.h., cycles were missed. It is not easy to say exactly at what frequency the drinking response oscillates for these inputs (Fig. 2*b*); it was less than the driving frequency, and of the order of 3.5 c.p.h. as shown by the model.

The role of the threshold for drinking may be as part of a mechanism which allows the animal to distribute its time between drinking and other systems that can control behaviour.

We thank D. A. Tonge for help in implanting cannulae, and the MRC for making this assistance possible.

One, Two or Three Connecting Links between Triassic and Jurassic Ammonoids?

It has long been recognized that the Jurassic and Cretaceous ammonoids are very different from those of the Triassic and it is generally concluded that the whole order Ammonoidea nearly became extinct at the Triassic–Jurassic boundary. More than a century ago Suess[1] recognized that one group, the phylloceratids, was common to both systems. Most authors[2–5] have accepted this view and have further concluded that the phylloceratids provide the only link between the faunas of the Triassic and the Jurassic. In taxonomic terms this is expressed by Arkell *et al.*[5] as follows: Jurassic and Cretaceous ammonoids comprise suborders Phylloceratina, Lytoceratina and Ammonitina. Of these only Phylloceratina extend back into the Triassic. In the Lower Triassic, Phylloceratina merge with Ceratitina, the dominant Triassic group, which became extinct at the end of the Triassic. It was the opinion of Arkell *et al.* that both Lytoceratina and Ammonitina were derived from Phylloceratina.

Wiedmann[6] has now brought forward a very different interpretation, indicating that both Lytoceratina and Ammonitina lived in Triassic times and that the faunal break is much less profound than supposed by all previous workers, with three groups (Phylloceratina, Ammonitina and Lytoceratina) crossing the boundary. Schindewolf, Shevyrev and Teichert, as mentioned below, also agree that the Lytoceratina extend back to the Triassic. Wiedmann's recognition of Ammonitina in the Triassic is wholly novel.

I suggest that there is still no satisfactory evidence that Lytoceratina and Ammonitina are represented in the Triassic faunas and that Wiedmann's conclusions are not justified.

The recognition of Lytoceratina in the Triassic is based on one specimen, named *Trachyphyllites costatus* by Arthaber[7]. To Arthaber, *Trachyphyllites* was a subgenus of *Monophyllites* (Phylloceratina). He noted resemblances between *Trachyphyllites* and Lower Jurassic Lytoceratina but attributed them to convergence. Later workers[2,8–12] have considered these resemblances to be of phylogenetic significance. There is now general agreement, which I do not dispute, that *Trachyphyllites* is a representative of Lytoceratina, but is it a Triassic ammonoid? N. J. Silberling has drawn my attention to good reasons for suggesting that it may be Jurassic, not Triassic. The unique specimen of *Trachyphyllites costatus* was collected by a Dutch expedition from a limestone block in Oë Bihati, about 2 km east of Baun in Indonesian Timor. Collections were made from numerous blocks in this river. Most were Triassic ammonoids but some of Jurassic age were also obtained. Individual blocks were designated by numbers and Greek letters. Their exact location in the river bed is shown on a map published by Burck[13]. Arthaber[7] gives Bihati lower case theta (ϑ) as the locality for *T. costatus* in his text, but as lower case delta (δ) on the plate description. With the exception of *Rhacophyllites fallax* Arthaber, which has the same ambiguous locality data, no other ammonoids have been recorded from block δ. Arthaber[7] wrote that Diener noted the occurrence of both Triassic and Jurassic ammonoids from Bihati δ. But in Diener's report[14] a mixing of Triassic and Jurassic ammonoids was recorded only from Bihati upper case theta (Θ). Diener makes no reference to Bihati δ. Burck's map shows both block δ and block Θ, but no ϑ. This suggests that both Θ and ϑ refer to the same block. There seems to be at least an even chance, therefore, that *Trachyphyllites costatus* came from a block (Θ = ϑ) which contained both Triassic and Jurassic ammonoids. The exact age of *Trachyphyllites* can only be considered uncertain. Nothing like *Trachyphyllites* has been found in Triassic rocks elsewhere, but comparable ammonites occur in the Lower Jurassic according to Spath[2] and Basse[8]. Extending the range of Lytoceratina into the Triassic on this occurrence alone seems unwarranted. *Trachyphyllites* is probably what it looks like, a Jurassic ammonite.

The alleged extension of Ammonitina back into the Triassic must now be considered. Wiedmann[6] describes a new genus, *Phyllytoceras*, based on Upper Triassic specimens from Iran and Austria. *Phyllytoceras* is classified as a member of a new family (Phyllytoceratidae) of Psilocerataceae (Ammonitina) by Wiedmann. He regards *Phyllytoceras* as the ancestor of *Psiloceras*, of the basal Jurassic Hettangian Stage; and possibly also the ancestor of Lytoceratina. *Phyllytoceras intermedium* Wiedmann, the only species known, is a smooth serpenticone. The suture line is ammonitic, with two lateral lobes, a dependent suspensive lobe, a non-lituid internal lobe, and a deep incision on the outer side of the external saddle. I submit that all these characters are found in the Gymnitidae, a family of Triassic Ceratitina. Many Gymnitidae are smooth serpenticones. They have ammonitic suture lines, with two lateral lobes, a dependent suspensive lobe and commonly a deep incision on the outer side of the external saddle[12]. Gymnitidae attain a large size and have a more deeply incised suture line than *Phyllytoceras*. *Phyllytoceras* is known only from small specimens, however, the largest being 4.5 mm in diameter, so the differences in degree of incision are probably not significant. The internal lobe of *Japonites* (generally considered a gymnitid) is known to be non-lituid[12], as in *Phyllytoceras*. Non-lituid internal lobes have also been illustrated for *Tropigymnites planorbis* (Hauer)[15] and *Arctogymnites sonini* Popov[16]. These two, if not Gymnitidae, are not far removed from members of the family. Wiedmann seems to be unaware that Gymnitidae have non-lituid internal lobes because he indicates that a lituid internal lobe is diagnostic of Ceratitina[17]. Also, he makes no comparison between the suture lines of *Phyllytoceras* and Gymnitidae. The non-lituid internal lobe of *Phyllytoceras* evidently influenced Wiedman in his decision to regard it as a representative of Ammonitina, but clearly, this character is not decisive. Wiedmann[6] has exposed the primary suture line of *Phyllytoceras*, showing it to have four lobes. The primary suture line of *Gymnites* and allied genera has not yet been described so the significance of this character of *Phyllytoceras* cannot be assessed at present. Most Triassic Ceratitina, however, have four-lobed primary suture lines[17]. Psilocerataceae, and most, if not all, other Ammonitina have five-lobed primary suture lines[17]. The four-lobed primary suture line of *Phyllytoceras*, therefore, in no way supports its assignment to Ammonitina. There seems to be no doubt that *Phyllytoceras* is a member of Gymnitidae, possibly an immature representative of *Gymnites* itself. Suture lines of Psilocerataceae[5,6,18] do not closely resemble those of *Phyllytoceras* and *Gymnites*. All have dependent suspensive lobes but the Psilocerataceae lack the deep incision in the external saddle that gives character to the suture lines of *Gymnites* and *Phyllytoceras*.

I conclude that there is no good evidence that Lytoceratina and Ammonitina are represented in the Triassic ammonoid fauna. The Triassic–Jurassic faunal break is as profound as believed by Arkell *et al.*[5] and there is still only one group, the phylloceratids, known to straddle the boundary.

Cranium of *Plesiadapis*

THE reconstruction by Szalay of the only known skull (CR 125, Muséum National d'Histoire Naturelle, Paris) of the Palaeocene primate *Plesiadapis* was presented[1] as differing from previous reconstructions[2-4] in the occlusal relationship of the enlarged procumbent incisors and in the relationship of the bones of the snout.

Szalay's principal contribution was his supposedly new location posteriorly of the point of occlusion of the lower incisors with the uppers. The incisor relationship illustrated by Szalay is not new, however; it is precisely that illustrated in the original reconstruction of this skull by Simons[2] (Fig. 1). Szalay refers to this 1960 reconstruction but does not discuss it, preferring to address his comments to a derived illustration which accompanied a popular article written later by Simons[3].

Reconstruction of the snout of this animal by Russell[4] was prefaced by the remark "L'écrasement subi a rendu difficile la détermination de la limite postérieure et dorsale des prémaxillaires". This remains true. Russell's discussion, together with Szalay's Fig. 2, support the original interpretation of bone relationships of the snout by Russell[4,5], not that newly presented by Szalay. A premaxillary-frontal contact is present in living mammals with procumbent *Plesiadapsis*-like incisors (compare the marsupial *Dactylopsila*, the primate *Daubentonia*, rodents and lagomorphs) and is probably related to the function of such incisors. Until better preserved material is discovered, Russell's original interpretation that the premaxilla makes contact with the frontal in *Plesiadapis* remains the most reasonable alternative.

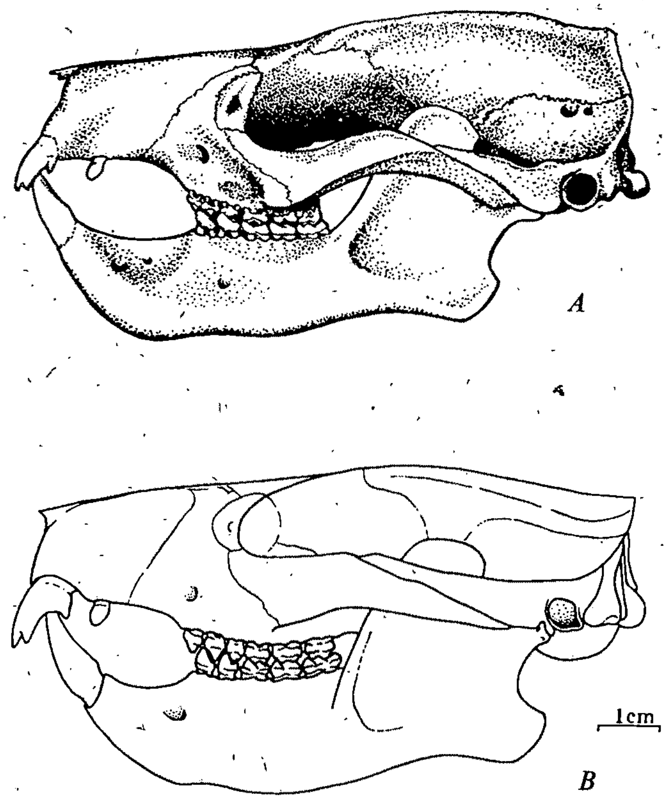

Fig. 1 Reconstructions of lateral view of skull of *Plesiadapis tricuspidens*. *A*, Original reconstruction by Simons (ref. 2); *B*, reconstruction by Szalay (ref. 1).

Szalay also criticizes the statement by Simons and Russell[6] that "only in Cheirogaleinae, among living and fossil Lemuriformes, is the os planum present" and cites Forsyth Major[7] as evidence for disagreeing with them. In fact, what Forsyth Major said was: "Amongst the Malagasy Lemurs a fairly large os planum is present in all the species of *Microcebus*. In the other genera the planum becomes fused with the palatal at a very early date". Thus Forsyth Major's evidence agrees with Simons and Russell's statement, not with Szalay's. A distinct os planum is present in mature skulls of Lemuriformes only in the Cheirogaleinae (including *Microcebus*) (see ref. 8 for a more recent discussion).

Szalay objects to the use of the presence of an os planum in the orbital wall as a diagnostic feature of the order Primates. As Le Gros Clark outlined[9], and Martin restated[10], any definition of primates must be based on a suite of characters, a "total morphological pattern" or a "total functional pattern", not all of which will be present in all forms included in the order. Absence of an os planum in certain early Tertiary primates and some living lemurs does not preclude using the presence of an os planum as one of a suite of characters defining the order primates; an os planum is present in most primates.

In short, Szalay's recent article contributes no addition to knowledge of the cranial or dental anatomy of *Plesiadapis*.

Ethmoid Component in the Orbit of Primates

SZALAY[1] has attributed to Forsyth Major[2] the statement that the ethmoid bone appears in the medial orbital wall of many Madagascar prosimians. But in fact, an orbital exposure (os planum) of the ethmoid is known only in *Cheirogaleus* and *Microcebus* among Lemuriformes. As Jones[3] and Kollman[4] have demonstrated, the element which Forsyth Major mistook for an os planum is the pre-nasopalatine part of the palatine bone.

The ethmoid of mammals is a cartilage-replacement bone which forms in the cartilaginous walls of the embryonic nasal chamber. In most non-primates, the ethmoid is covered by membrane bones laid down by the periorbita that lines the eye socket. If the orbits are very large or very close together, the periorbita is pressed against the nasal capsule in the

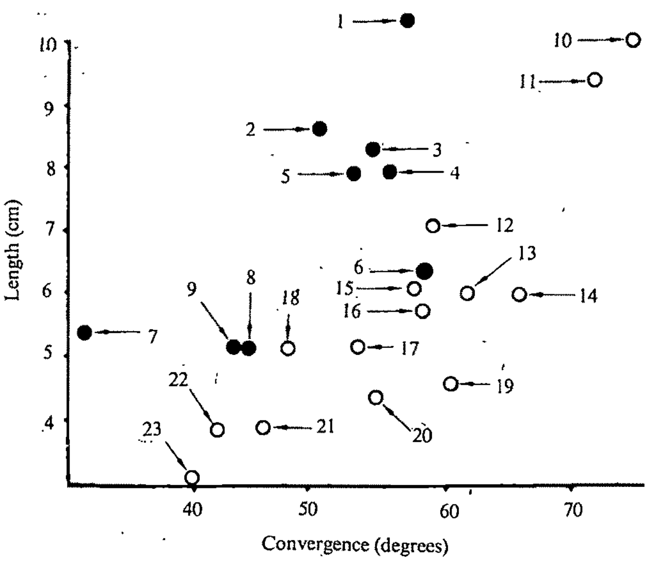

Fig. 1 Sample means of orbital convergence and prosthion-inion length in anthropoid and prosimian primates. "Convergence" is defined as the dihedral angle between the mid-sagittal plane and the plane of the medial orbital margin. Open circles represent species with an os planum in the medial orbital wall. Numerical designations (and sample sizes) of sampled species: 1, *Indri indri* (n=6); 2, *Lemur macaco* (6); 3, *Lemur catta* (6); 4, *Propithecus verrauxi* (6); 5, *Daubentonia madagascariensis* (2); 6, *Hapalemur griseus* (8); 7, *Phaner furcifer* (2); 8, *Lepilemur mustelinus* (6); 9, *Avahi laniger* (4); 10, *Cercopithecus nictitans* (6); 11, *Cebus apella* (6); 12, *Galago crassicaudatus* (6); 13, *Aotus trivirgatus* (6); 14, *Callicebus moloch* (24), 15, *Perodicticus potto* (6); 16, *Nycticebus coucang* (7); 17, *Nycticebus pygmaeus* (5); 18, *Cheirogaleus major* (4); 19, *Loris tardigradus* (6); 20, *Callithrix jacchus* (6); 21, *Tarsius syrichta* (6); 22, *Galago senegalensis* (6); 23, *Microcebus murinus* (6). Data from ref. 7.

embryo, and the ethmoid appears in the medial orbital wall of the adult.

Primates with an os planum are either small animals with relatively large eyes (as a result of negative allometry), or animals with pronounced orbital convergence, or both (Fig. 1). With increase in body size and consequent decrease in relative eye size, orbit and nasal fossa "compete" less for the available cranial volume, and the ethmoid may disappear again beneath laminae of the periorbital membrane bones. This sometimes happens in large gorillas[5], and may have occurred in the evolution of larger Madagascar primates from *Microcebus*-sized ancestors. If the last common ancestor of the extant primates was a small animal with large and convergent orbits, it probably had an ethmoid component in the medial orbital wall. It seems as likely that *Daubentonia*, *Phaner*, the lemurines and the indriids have lost the os planum independently, as that *Microcebus*, *Cheirogaleus*, *Tarsius*, the Lorisiformes and the anthropoids have acquired it independently. Although *Necrolemur* is said to lack an os planum, the medial orbital wall of *N. antiquus* as reconstructed by Simons and Russell[6] strongly resembles that of an adult *Microcebus* after the disappearance of the frontoethmoidal suture[4]; a distinct os planum may well have been present in juvenile *Necrolemur*.

Is Vertesszöllös II an Occipital of European *Homo erectus*?

THE taxonomy of the two human fossils discovered at the Intermindel occupation site of Vertesszöllös in western Hungary has been a topic of considerable interest. The fragments of a deciduous tooth representing the first individual (V1) were judged by Thoma to be indistinguishable from deciduous teeth from Choukoutien[1], but he later concluded that the second individual (V2), represented by an occipital fragment, is a member of the taxon *Homo sapiens*[2,3]. He places V2 on the lineage leading to Swanscombe, in preference to separate lineage leading to the neandertals.

The "chopper-chopping tool" industries at Vertesszöllös and at Choukoutien are quite similar[4], which leads to the somewhat bizarre conclusion that two different hominid species are associated with a chopper-chopping tool industry at Choukoutien (*Homo erectus*) and at Vertesszöllös (*Homo sapiens*), and the same two species are associated with a hand axe industry at Ternifine (*Homo erectus*) and Swanscombe (*Homo sapiens*). Because the industry at Vertesszöllös is, for all intents and purposes, the same as that at Choukoutien where *Homo erectus* material from the same time period has been found[5], and because Thoma convincingly demonstrated that V1 cannot be distinguished from this *Homo erectus* sample[1], it is of some interest to examine his basis for placing V2 in *Homo sapiens*[2,6].

In his most recent analysis, Thoma concludes[2] that "the majority of gross morphological features of Vsz. 2 is Archanthropic in character". Most of these features are characteristic of *Homo erectus*[7,8], and measurements of thickness are completely within the *Homo erectus* range, usually falling between the values for the material from Peking and Java. The inion angle of the occipital is quite low. The nuchal torus is heavy, and extends laterally across the entire bone in the fashion of almost every other *Homo erectus* specimen, and unlike australopithecines, neandertals, modern men, and the other early European specimens—Swanscombe and Steinheim. The torus is quite high. The inion is considerably higher than the internal occipital protuberance which indicates the extent of the nuchal musculature, and suggests that the individual was large and probably male. The total morphological pattern is far more similar to a large *Homo erectus* than it is to a large neandertal. The two other early European crania are later, and are possibly female. Comparisons are therefore misleading.

In contrast, there are few reasons for placing the occipital in *Homo sapiens*, Thoma's *Paläanthropus* grade. Thoma claims only two: a high and fairly curved profile of the upper part of the occipital squama projected in the sagittal plane, and a cranial capacity significantly greater than *Homo erectus*. The sagittal curvature of the upper part of the squama is indicated by the index of the lambda-inion arc to the lambda-inion chord. In V2 this index is 108.2; a sample of nine *Homo erectus* specimens average 105 and range from 102.3 to 108.4 (s.d. = 1.8).

The high profile of the upper part of the squama is misleading, for the angle at the inion is not particularly great. Its value, 103°, is equal to or less than those of almost every occipital in the Peking group, and is considerably smaller than the angle in Swanscombe (118°), a more recent European specimen. The upper squama matches Peking crania such as 10 quite well in sagittal profile, except for the fact that it extends more anteriorly, and consequently is higher. There are, however, wormian bones in the vicinity of lambda which make it impossible to determine exactly where lambda is. Thoma chose the most anterior point, whereas Martin suggests[9] the point where lines smoothly approximating the course of the lamboidal suture cross each other. This point is more posterior, and consequently lower, in the V2 occipital. Use of the proper point would diminish the two chords which now fall outside the *Homo erectus* range by being too large, lambda-inion and lambda-opisthion.

Table 1 Comparison of Regression Parameters, Fit and Correlation for Lambda-Opisthion Chord and Cranial Capacity

		Slope	Intercept	Correlation	Percentage error of regression fit	Sample size
Homo erectus	(1)	23.77	−1,052.4	0.95	3.6	5
	(2)	22.30	−910.7	0.89	4.1	7
Neandertals		30.36	−1,344.3	0.82	6.4	14
Homo sapiens		25.71	−1,047.7	0.83	5.8	200

Table 2 Calculation of *Homo erectus* Cranial Capacities by Regression with the Lambda-Opisthion

Specimen		Lambda-opisthion chord (mm)	Actual cranial capacity (cm^3)	Calculated cranial capacity by regression		
				Wolpoff (n=5)	Wolpoff (n=7)	Thoma
Java	(1)	78*	850		822	877
	2	75	755	731	753	797
	4	78	750	802	822	877
	6	81*	975		891	957
Peking	3	84	915	944	960	1,037
	11	86	1,015	992	1,006	1,090
	12	87	1,030	1,016	1,029	1,117
Average absolute difference				32	37	68
Percentage difference				4%	4%	8%
Calculated Vertesszöllös capacity				1,325	1,328	1,463

* Estimated.

Thoma estimates the cranial capacity of V2 by means of a regression equation[2,6] which relates the lambda-opisthion chord to cranial capacity. Of the twelve specimens used by him, only five were *Homo erectus*, and with these he mixed five Solo crania and the Swanscombe and Broken Hill specimens. He conservatively uses the lower 95% confidence limit and concludes that the capacity must be greater than 1,400 cm^3, using his lambda-opisthion measure of 102 mm, or greater than 1,350 cm, using Tobias's measure of 100 mm.

I have calculated separate regressions for *Homo erectus*, neandertals, and 200 *Homo sapiens* specimens chosen at random from publications in *Biometrika*. Of the seven available specimens of *Homo erectus*, the positions of opisthion were uncertain in Java 1 and 6 and have been estimated in the literature. Regressions were calculated for the *Homo erectus* sample both with and without these specimens. The equations and correlations are given in Table 1.

The correlation for the regression using the small (unestimated) *Homo erectus* sample alone is greater than Thoma's correlation of 0.93 for his entire sample. The correlation value for the neandertals is lower, but this calculation used all of the published neandertal measurements (n=14), instead of only a few (n=6).

Table 2 indicates a test of the regressions by predicting the known cranial capacities in the *Homo erectus* sample. The percentage error for *Homo erectus* both with and without the two questionable specimens is close to 4%, but the percentage error of Thoma's equation when used to predict capacities only for *Homo erectus* is twice as great. The percentage error of Thoma's equation used to predict only the five specimens for which opisthion is known is greater still; almost 10%.

The archaeological evidence, the morphology of VI from the same site and by Thoma's admission most features of V2 suggest that the specimen is *Homo erectus*. It thus seems reasonable to use a regression based on *Homo erectus* specimens to estimate its cranial capacity. The regression for either sample gives almost identical estimations for V2, using Tobias's value of 100 mm for the lambda-opisthion chord. Because the actual value of the chord may be less, the estimation of about 1,325 cm^3 is a maximum.

Is the capacity of V2 large enough to be outside of the expected range of *Homo erectus* variation? The 95% range cannot be used because it is too large to be meaningful (±345 cm^3). The estimate is only 100 cm greater than the Peking 10 capacity. A *t* test comparing V2 with a sample of cranial capacities[10] of twelve *Homo erectus*, excluding the V2 value itself, indicates that V2 is not significantly different from *Homo erectus* on the 5% level. Along with all of the Peking crania, the capacity is, of course, within the range of variation for *Homo sapiens*.

In sum, it seems likely that V2 is the occipital of a *Homo erectus*. V2s similarity to the Swanscombe material is not surprising in view of the strong possibility that the English cranium is a member of the same lineage somewhat later in time.

New Carbon-14 Evidence for Six Hundred Years Old *Canna compacta* Seed

THE longevity of a viable seed of *Canna* considered to be about 550 years old[1–3] has been questioned by Godwin[4]. The specimen, enclosed in a *Juglans australis* nutshell forming part of a rattle necklace was collected from tomb 92 in Santa Rosa de

Tastil, Argentina. New carbon-14 dates presented here, on the nutshell and a trash heap, confirm this to be the oldest viable seed known.

Santa Rosa de Tastil is the first archaeological town dated in the Argentine north-west (24° 25′ S, 65° 50′ W, 2,800 m altitude). In the site were excavated remains of a conglomerate of about 400 dwellings with an evolved network of streets and squares. About 100 tombs and several contemporaneous trash heaps show that occupation was continuous.

The first radiocarbon analysis, on wood charcoal[3] collected in heap 1 together with cameloid bones, dated the site as 530±30 yr BP (years before present defined[5,6] as before AD 1950). Sivori *et al.*[1,2] reported in 1968 the germination and growth of one of the *Canna* seeds found inside the nutshells. The plant has since been growing healthily[7,8] and has reached a height of about 2 m. It flowered and was identified as *Canna compacta* Rosc., by H. Fabris at the University of La Plata. The flowers were self fertilized and produced seeds, which were sown. These germinated with fewer geotropic irregularities than their archaeological ancestor[1,2,7,8].

The kind of evidence about the age of the seed demanded by Godwin and Willis[4,9] is the most desirable if reliable dates are to be found for viable seeds. It involves assaying the carbon-14 of germinating seed before the seedling begins to photosynthesize[4,9]. This is, however, a destructive analysis, requiring early interruption of growth and combustion of the seedling. This was not feasible in the present case: (1) because of the interest in observing the plant growth and eventually determining its species; (2) the organic chemicals used to stimulate germination might have altered the radiocarbon content of the seed by assimilation or by isotopic exchange, and (3) the amount of material—several grammes of carbon—necessary to provide a precise date was not available. The weight of each of the three *Canna* seeds found was about 200 mg. With a yield of carbon only a fraction of the total weight, dating could have been possible only in a "mini-counter"[10]. This, however, would have not been useful because of the large standard deviation of such a measurement (1σ=several hundred years; see Fig. 2 of ref. 10).

Fortunately there were two indirect ways of radiocarbon dating the seed: by analysing the nutshell and the charcoal remains. These data could be interpreted on the basis of the archaeological evidence now being documented[8] by Sivori *et al.*[1,2], and summarized here. (1) The ceramics and other remains, such as the bone artefacts and textiles found in tomb 92 associated with the rattle necklace, are of the same style as those found in heap 1; (2) there are no signs of any intrusions or other perturbations in the material accumulated in the trash heap; (3) the seed has to be contemporaneous or older than the *Juglans* nutshell, because the seed could only have been introduced into the nutshell as long as the nut was still unripe. This was done through a slit cut into it, which after hardening contributes to the characteristic sound of the rattle. Similar rattles have been described by Casanova and von Rosen[11,12], for pre-Inca sites.

By measuring the carbon-13 content of the samples[3,19] all radiocarbon analyses were corrected for isotopic fractionation[13] to avoid errors which could be as much as 250 yr[14–16,3,17]. The carbon-14 dates obtained in BP were transformed to true, historical or calendar years AD. This conversion was done by means of a calibration curve based on measurements of carbon-14 in tree rings. The ambiguity[4,18] between the scales BP and AD caused by the fluctuations of the atmospheric content of the isotope can thus be removed. As the curve of Lerman *et al.*[19] based on Argentine samples does not extend further back than 550 yr BP, we used the curve of Stuiver and Suess[20] for the Northern Hemisphere, modified to account for the observation that Southern Hemisphere samples seem to be about 40 yr older[19,21].

The nutshell was dated as 620±60 BP (GrN–5818)*, converted to AD 1362±73. Heap 1 was divided in seven stratigraphic layers of 20 cm thickness each. Charcoal from layers 1, 4 and 7 was radiocarbon dated: 580±35 BP (GrN–5807), 650±45 BP (GrN–5808), and 635±30 BP (GrN–5809), respectively. These dates and that previously reported[3] (530±30 BP (GrN–5147)) also dates layer 1. The converted dates are: AD 1418±19 for layer 1 (weighted average of the two samples); AD 1336±50 for layer 4; AD 1349±41 for layer 7. Our statistical analysis suggests that the accumulation of the whole trash heap took about 90 yr[22], and that the longest accumulation period, with a confidence level of 95% (2σ interval), was AD 1282 to AD 1467 (ref. 22). As we have shown, the rattle as well as the seed were contemporaneous with the trash heap. The antiquity of the nut ranges from AD 1216 to AD 1508 (2σ interval). The nutshell and the trash heap dates are thus consistent.

The carbon-14 analyses also agree with the dating based on the archaeological and historical chronologies for the region: the excavated potsherds belong to the Late Ceramic Period which dates between AD 1000 and AD 1450, and the absence of Inca objects determines as *terminus ante quem* AD 1450 to AD 1550.

We conclude therefore that the seed from Santa Rosa de Tastil was about 600 yr old when germinated. Compared with documented lists[4,9,23,24] this is the oldest known viable seed. The resistance of *Canna* seeds to hard treatment has been reported[25] (for example, germination of seeds threaded forming a rosary, and of seeds kept about 30 yr in a herbarium).

We are indebted to the Groningen Physics Laboratory for the isotope analyses. This work was begun while J. C. L. was on the staff of that laboratory.

Isozyme Variation under Selection in *Zea mays*

THE extent of polymorphism in genetically determined isozyme variants (allozyme variation) in natural populations raises the issue of its adaptive significance. It was originally thought that this variation is neutral with respect to fitness[1], but recent evidence supports the assertion that its maintenance involves a selective component[2]. If an allelic substitution yields an enzyme with altered properties[3], maintenance by selection in natural populations may result in a distinct geographic distribution of allele frequencies. Such a pattern has been described[4] in the case of a serum esterase polymorphism in the freshwater fish *Catostomus clarkii*.

Isozyme gene frequencies were examined in a symmetrical set of lines after prolonged selection for and against a specific metabolic property. We did this by assaying enzyme polymorphism in the highly selected strains of maize from the breeding experiment established by Hopkins[5]. From 163 open-pollinated ears of the local maize variety Burr White, he set up four strains (HO, LO, HP and LP) which were selected for high and low seed levels of oil and protein respectively. The long term responses to selection in these Illinois strains are now considered classic examples in both evolutionary theory[6] and plant breeding[7]. Reverse selection[5] has displayed considerable genetic variance persisting after forty-eight generations, and variance analysis[8] after sixty-five generations. Thus, a comparison of electrophoretic variants in these strains may provide a test of whether isozyme variants are selectively neutral.

Seedlings of the four directional strains (HO, LO, HP and LP) and Leng's four reversed strains (RHO, RLO, RHP and RLP) were assayed for E_1, E_3, E_4 and E_{12} (esterases), alcohol dehydrogenase (*Adh*) and peroxidase (*Px*) by techniques described before[9]. Twenty generations of selection have elapsed since the four reverse lines were isolated[5] in 1948. Sample size exceeded fifty seedlings except for LO of which there were only thirty because it germinated poorly. The gene frequency estimates (Table 1) show that each of the eight strains is genetically distinct. More than two strains are polymorphic for each locus: the *S* and *N* alleles at the E_1 and *Px* loci and the *S* and *F* alleles at the E_3, E_{12}, *Adh* and E_4 loci, while the low protein (LP) strain was polymorphic for the *S* and *N* alleles at the E_4 locus.

Table 1 Gene Frequency Estimates of the Slow (S) Allele for Six Isozyme Loci in Eight Selected Strains of Maize

Selected strain	E_1	E_3	E_4	E_{12}	*Adh*	*Px*
Oil content						
High (HO)	0.93	1.00	0.00	0.29	0.33	0.00
Low (LO)	0.57	0.00	1.00	0.83	0.04	1.00
Reverse high (RHO)	0.14	0.76	0.50	0.15	0.29	0.51
Reverse low (RLO)	0.14	0.00	0.34	1.00	0.00	0.23
Protein content						
High (HP)	0.00	0.49	1.00	0.00	0.00	0.50
Low (LP)	1.00	0.00	0.30*	0.00	0.00	0.00
Reverse high (RHP)	0.00	0.18	1.00	0.00	0.74	0.81
Reverse low (RLP)	0.28	0.00	1.00	0.00	0.15	0.12

* Polymorphic for the *S* and *N* alleles.

The mating design of the experiment[5] has enforced outcrossing between selected ears within a strain. To test for the Hardy–Weinberg genotypic distribution, estimates of the fixation index were made for each variable locus in each strain. The fixation index (*F*) is a measure of the proportionate deficiency of heterozygotes at census, and absolute values of *F* greater than $1.96/N^{\frac{1}{2}}$ ($=0.28$) are required to reject the null hypothesis[10] that $F=0$. The values shown in Table 2 conform to the Hardy–Weinberg distribution.

Table 2 Fixation Index Estimates for Six Isozyme Loci in Eight Selected Strains of Maize

Selected strain	E_1	E_3	E_4	E_{12}	*Adh*	*Px*
Oil content						
High HO	−0.08	—	—	0.10	−0.07	—
Low LO	−0.24	—	—	−0.21	−0.05	—
Reverse high RHO	−0.03	0.18	0.06	−0.02	−0.09	0.03
Reverse low RLO	−0.17	—	−0.11	—	—	−0.02
Protein content						
High HP	—	−0.21	—	—	—	0.06
Low LP	—	—	−0.03	—	—	—
Reverse high RHP	—	−0.08	—	—	−0.07	−0.11
Reverse low RLP	0.13	—	—	—	−0.18	−0.14

Selection of twelve ears per strain in this design reduces the effective population size (N_e) to no less than thirty individuals. Assuming that by 1948 the rate of neutral fixation of loci had reached the steady state ($1-1/2N_e$) of variable loci would remain unfixed after each generation. Therefore $(59/60)^{20} \simeq 0.7$ of the variable neutral loci in 1948 would remain unfixed after twenty generations.

Consider the hypothesis that all the allozymic differentiation among the strains is attributable to genetic drift. The following points argue in favour of this hypothesis. First, half of the twelve comparable results at specific loci in Table 1 do not directly correspond to directionally consistent changes. For example, the $E_1{}^s$ allele is less frequent in the reverse low oil (RLO) strain than in the low oil (LO) strain, whereas it is most frequent in the high oil (HO) strain. Second, when reverse selection began, there were at least eighteen loci still variable because eighteen of the twenty-four paired comparisons between the current forward and reverse strains are dissimilar. Of these, twenty-four out of thirty-six remain unfixed in the current generation, and this proportion agrees well with that predicted by drift.

Yet other observations suggest that a selective component may be superimposed. First, of the twelve fixations occurring in the last twenty generations, nine were fixed under forward and only three under reverse selection (one-tail probability of 0.07). Second, the assumption of the steady state and the minimal estimate of N_e have probably inflated the estimate of the effect of drift in these strains. And Table 1 shows that while on average the reverse selection strains vary at more loci than the forward strains (a mean of 3.75 c.f. 2.25), the same difference occurs between the oil strains as a group and the protein strains. Such biases could arise from selective rather than neutral fixation.

These results are acceptable on the hypothesis of purely neutral drift but the deviations suggest that isozyme variants are not entirely neutral to selection.

I thank Drs J. W. Dudley and D. E. Alexander for seeds and Dr J. R. G. Turner and Professor M. H. Williamson for discussion.

Shrub Ecotypes in a Salt Desert

A SALINITY gradient extends from the highly saline beaches of the Great Salt Lake of Utah to the surrounding non-halomorphic soils, with a correlated vegetation gradient in which a succession of plant communities grows in concentric zones. The chief communities, in decreasing order of soil salinity, are dominated by (1) *Salicornia–Allenrolfea;* (2) *Sarcobatus vermiculatus;* (3) *Atriplex–Eurotia;* and (4) *Artemisia tridentata*[1]. Within these communities are perplexing local distributions of co-dominant species. Typical communities within the *Atriplex–Eurotia* zone include pure *Atriplex confertifolia, Atriplex–Eurotia,* pure *Eurotia lanata, A. confertifolia Artemisia spinescens–Eurotia* grass, and pure *Atriplex nuttallii.* Although these communities are separated by sharp ecotones, local soil variations are insufficient to explain the distribution of the different plant communities[2].

We have investigated first, the possibility that genetic differences between local populations of *A. confertifolia* and *E. lanata* explain their distribution in or near the five communities within the *Atriplex–Eurotia* zone. Second, we investigated the contribution of genetic differences to the wide tolerance to salinity shown by *A. nuttallii,* which occurred locally in pure stands along the whole salt gradient. Populations of *A. nuttallii* were sampled from the *Salicornia–Allenrolfea* zone, from two communities in the *Sarcobatus* zone, and from the *Atriplex–Eurotia* zone in Curlew Valley, north of the Great Salt Lake.

Sample plants of *A. confertifolia* and *E. lanata* from within the *Atriplex–Eurotia* zone, and of *A. nuttallii* along the salt gradient were removed in blocks of native silt with minimal root damage, and were grown for at least 6 weeks in a glasshouse. Initial soil conductivities were recorded (Table 1). The plants were then grown at 27° C with a 16 h photoperiod in nutrient culture[3] with high levels of salt (10 mM) and boron (0.1 mM) to simulate the average soil condition. Concentrated sodium nitrate solution (16.5 mM) was added to increase plant growth rate. These cultures had conductivities of approximately 50 mmho.

Three measurements were made on six plants from each site in November 1970. These were (*a*) mean shoot dry weight increase in 3 weeks ($\overline{W}_S$); (*b*) relative leaf growth rate[4] ($\overline{R}_L$), and (*c*) nitrate reductase activity ($\overline{A}_N$)[3]. These were chosen as representing different levels of expression of plant activity.

Plants of *E. lanata* from the *Atriplex-Eurotia* zone had a large yield and a very active nitrate reductase system, but variability between populations in these parameters was small (Table 1). On the other hand, populations of *A. confertifolia* demonstrated marginally significant ($P=0.05$) differences in both yield and nitrate reductase activity between sites. The pure stand (P) plants had the lowest dry weight increase, whereas the *A. nuttallii* site (N) plants had lowest nitrate reductase activity. This implies that genetic differences did exist between the different populations of *A. confertifolia.* This species is dioecious with vegetatively distinct sexes, and it was also found that female plants yielded more than males ($P<0.05$).

Populations of *A. nuttallii* from along the salt gradient demonstrated significant differences ($0.05>P>0.001$) in all parameters (Table 1). Further, plants of *A. nuttallii* from the *Atriplex–Eurotia* zone had distinctly smaller leaves than the other populations. In the other sites, R, K and S (Table 1) *A. nuttallii* appeared to be morphologically uniform. Several subspecies, or possibly true species, have been described within the *A. nuttallii* complex[5], so that the distinct morphology and physiology of the plants in the *Atriplex–Eurotia* zone may indicate that they should be accorded subspecific status.

In spite of the large variation in soil conductivity within the *Sarcobatus* zone (Table 1), its two *A. nuttallii* populations (R and K) did not differ significantly. The *A. nuttallii* population from the *Salicornia–Allenrolfea* zone, however, was lower in yield, leaf growth rate and nitrate reductase activity than in the *Sarcobatus* zone plants. Three distinct populations of *A. nuttallii* therefore existed along the salt gradient, which may account for the wide salt tolerance of this species.

Table 1 Soil and Yield Characters of Three Salt Desert Species

	E. lanata				*A. confertifolia*			
Site	Soil con-ductivity	$\overline{W}_S$	$\overline{R}_L$	$\overline{A}_N$	Soil con-ductivity	$\overline{W}_S$	$\overline{R}_L$	$\overline{A}_N$
Pure stand (P)	0.8	18	0.35	235	10	8	0.15	35
Atriplex–Eurotia (M)	0.8	15	0.25	260	0.8	12	0.35	48
Near *A. nuttallii* (N)	1.4	16	0.15	278	1.4	16	0.37	11
Atriplex–A. spinescens–Eurotia grass (G)	1.0	18	0.18	272	1.0	12	0.37	82
SE	—	3.4	0.08	43	—	1.8	0.10	22

		A. nuttallii		
Site	Soil conduc-tivity	$\overline{W}_S$	$\overline{R}_L$	$\overline{A}_N$
Atriplex–Eurotia zone (N)	1.4	10	0.39	29
Sarcobatus zone (R)	5.2	17	0.60	106
Sarcobatus–Suada (K)	96	21	0.60	173
Salicornia–Allenrolfea zone (S)	121	14	0.42	9
SE		3.2	0.05	24

Soil conductivity is given in mmhos; $\overline{W}_S$, dry weight (mg) per shoot; $\overline{R}_L$, relative leaf growth rate; $\overline{A}_N$, nitrate reductase activity (mM $NaNO_2$/g fresh weight/h).

The variation in nitrate reductase activity as well as in yield and leaf growth rate in *Atriplex* but not in *Eurotia* suggests that in *Atriplex,* as in the Gramineae[6], nitrate reductase activity may be inherently variable. All of the three parameters were sufficiently variable to indicate considerable genetic variation in the *Atriplex* species studied. This contrasts with the finding of Hannon and Bradshaw[7] who reported that two co-existing maritime grasses were in a similar state of evolutionary adaptation to salinity. Our work suggests that these three desert chenopods, *A. confertifolia, E. lanata* and *A. nuttallii,* differ considerably in their state of evolutionary diversification. Indeed, the observation of interspecific hybridization in *A. nuttallii*[5] indicates that this species is in a very active state of evolution, and this probably accounts for its wide distribution.

Investigations are continuing with clones of the different populations growing in different environments (particularly different salinities) to test the adaptive nature of the population differences. This work and the possibility of genetical experiments in the future, however, is limited by the slow growth of woody *Atriplex* clones.

Flow of Red Blood Cells stopped by Ultrasound

ULTRASOUND has applications in physiotherapy in the treatment of musculoskeletal disorders[1], and recent findings indicate a potential value as a local anabolic agent[2-4]. It is used to detect tumours[5] and foetuses[6], while a further application lies in measuring the rate of blood flow in terms of corpuscular velocity[7,8]. The increasing use of ultrasound on human tissues has led to concern for possible hazards. It is essential that safety limits are determined accurately and that the interactions of ultrasound with living tissues are investigated so that they can be predicted when ultrasound is used within these limits. Largely in this connexion, we are investigating the effects of low intensity ultrasound on blood circulation in living tissues and wish to report a striking finding: the aggregation of red blood cells into stationary clumps in the radiation field (Fig. 1).

A chick embryo at the 3.5 day stage of incubation, together with its extra-embryonal membranes, was dissected free from the yolk in such a way as to keep the sinus terminalis intact, and placed in a saline-filled irradiation chamber[9] maintained at 37° C by a heated microscope stage, and consisting of a shallow rectangular metal tray fitted with a strip transducer at one of the shorter ends. The wall at the end opposite the transducer could be faced with either a reflector or with various combinations of absorbing materials. There was a central viewing area of thin glass over which the embryo was placed with its attached extra-embryonal membranes lightly stretched. The heart beat continued apparently normally for several hours in this preparation. The flow of red cells through the vessels of the chick and its associated membranes were viewed with a light transmission microscope. The ultrasonic field was monitored by a small, sensitized, thermistor probe which could be positioned at any point in the radiation field by means of a micromanipulator attached to the irradiation chamber.

We found that when particulate matter was suspended in the saline it aggregated into clumps arranged in vertical planes at right angles to the direction of propagation of the ultrasound. These aggregates were spaced at half wavelengths throughout the field. When the embryo was placed in the chamber, we found that above certain threshold intensities the blood cells in the developing vessels aggregated in a similar manner, and in some cases circulation was arrested. Red cell stasis was temporary, for the clumps broke down when irradiation ceased.

So far we have used only continuous 3 MHz irradiation. Threshold intensities for red cell aggregation are apparently determined by the nature of the vessel. When the ease of aggregation is compared in adjacent arteries and veins of similar bore, the threshold intensity is significantly lower in the vein than in the artery ($d = -1.22$, $N = 9$, $t = -5.8568$, $P < 0.0005$). Red cell stasis occurred more readily in large bore veins than in those of small bore. In arteries near the heart the situation was more complex because the red cell clumps are affected by pressure changes at each heart beat.

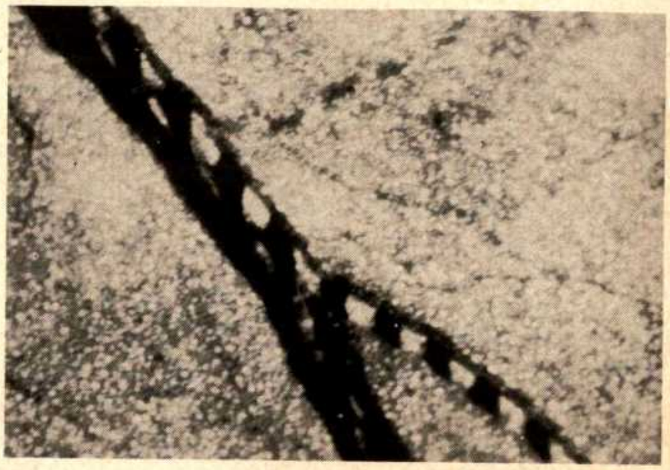

Fig. 1 Surface view of the area vasculosa of a chick embryo at the 3.5 day stage of incubation demonstrating ultrasonically induced red cell stasis (× *c.* 26).

When stasis was complete red cell aggregates were sharp-edged (Fig. 1). In conditions producing incomplete stasis, red cells could be seen breaking away from the downstream edges of the bands only to be trapped at the upstream edge of the next band. When irradiation ceased each band assumed the parabolic profile typical of Poiseuille flow before dissolution was complete (Fig. 2).

The fact that the aggregates were sharp-edged suggests that the red cells were not held together simply as a result of standing wave formation. We consider that Bernoulli attractions may be involved. If reflexion played a more important role in aggregate formation than simply determining the position of the aggregates in the radiation field, then one would expect a continuous gradation in red cell density between adjacent aggregates rather than the sharp limits that we have found. Other evidence also suggests that reflexion is a minor component of the forces producing aggregation. Masking the terminal reflector, the wall of the chamber opposite the transducer, by putting an absorber in front of it, did little to affect the threshold intensities required to produce aggregation. When the chamber was replaced by a tank lined by absorbers in which reflexion was minimal, linear aggregation of the red cells in the blood vessels still occurred. These results are interesting because they indicate that a strong reflected wave, such as might be obtained in medical ultrasonic usage at the interface between a soft tissue and air or bone, is not essential for the production of red cell stasis. It seems that only a minor change in acoustic impedance between one tissue and another is sufficient to trigger off the response.

The direction of the blood vessel, relative to the direction of propagation of the ultrasound, is also important in determining the effect on red cell motion. If the vessel is aligned parallel to the ultrasonic field stasis is readily evoked. If the vessel is at right angles to it then the red cells continue to flow within the cell aggregates.

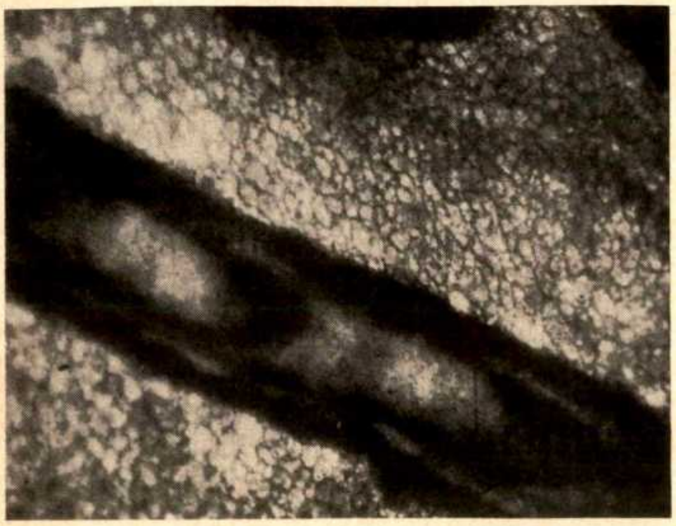

Fig. 2 Parabolic profile of dissociating red cell aggregates in a vein (× *c.* 186).

One serious effect of red cell stasis in arteries and arterioles is that the tissues supplied by them will be exposed to conditions of reduced oxygen availability. We suggest that this can be minimized by moving the treatment head during ultrasonic irradiation so that the direction of the vessels relative to the direction of propagation of the ultrasound is continuously varied. When this is not possible then the dose parameters should be kept below those producing red cell stasis in the major vessels. We also suggest that the possibility of interference with red cell flow be considered when Doppler probes are used to monitor the circulation of the blood.

We thank Mr Kevin Fitzpatrick and the Department of Medical Photography for assistance with photography, the Medical Research Council and the Wellcome Trust for financial assistance, and Professor R. Warwick for advice and encouragement.

Defence and Territorial Behaviour dissociated by Hypothalamic Lesions in the Rat

IT has been pointed out that much of the literature on brain mechanisms of aggression fails to distinguish between different kinds of aggressive behaviour, and that this may account for some of the apparent contradictions in different publications[1]. In the experiments reported here the effects of hypothalamic lesions were measured on two different types of aggressive behaviour: defence behaviour, which consists of a defensive upright posture and boxing in the shock box; and territorial behaviour, which consists of the offensive side posture and the full attack posture with biting and kicking by a socially isolated home rat against an intruder. These postures associated with social interactions are quite stereotyped in the rat. They are also present in modified form in other rodents and have been illustrated and catalogued previously[2].

We used adult male hooded rats, raised in the laboratory. Fighting in response to foot-shock (defence behaviour) was elicited by placing a pair of rats in a 'Plexiglas' cage 20 × 15 cm with an electrified grid floor. Each trial consisted of a series of twenty 60 cycle a.c. shocks lasting 0.5 s and delivered once every second. A grid scrambling device was used to guarantee that the rats could not escape the shock by standing on certain pairs of grids. Fighting threshold was determined by the titration method; that is, shock intensity was raised in a trial after one in which the rats did not fight and was lowered after one in which they did fight. Fighting was defined as defensive upright posture and boxing by both rats in the pair. Among normal rats these were the predominant responses seen, although at high shock intensities the rats sometimes bit at each other or leapt and rolled over together biting and kicking. Behaviour similar to the offensive side posture and full attack posture was not exhibited by normal rats in the shock box.

Territorial behaviour was obtained from rats that had been socially isolated for at least 1 week in a large home cage (1.4 m^2 of space on six levels with connecting ramps). Fighting, defined as offensive side posture and/or the full attack posture with biting, was exhibited against a male intruder placed in the home cage. The behaviour was quantified by determining the number of minutes in which fighting occurred during the 10 min period after the first occurrence. If no fighting occurred after 30 min, the trial was terminated.

All pairs of rats tested in the shock box showed rearing and boxing. Some rats did not fight off an intruder in the territorial experiment, however, and they were not used in the study.

Testing a rat in the shock box inhibited it from showing territorial fighting characteristics in the home cage. The rat seemed to become conditioned in the shock box to expect pain when approached by another rat. For this reason, the experimental animals were not tested pre-operatively in the shock box, but only after the initial post-operative tests had been carried out in the territorial situation. Post-operative results in the shock box were compared only with results in normal controls.

Lesions were placed in the hypothalamus by stereotaxic procedure using a radio frequency lesion maker. Surgery was performed aseptically on animals anaesthetized with 'Nembutal' (60 mg kg^{-1}) and the rats were allowed 3 days for recovery before behavioural testing. Lesions involving the lateral hypothalamus abolished spontaneous feeding, in which case the animals were maintained by stomach tube feeding. Lesions were assessed on cresyl violet stained serial frozen sections.

Only rats with symmetrical lesions were included in the study. The experimental results (Fig. 1) depended on whether the lesion substantially destroyed the medial hypothalamus (six rats), the lateral hypothalamus (six rats) or both (six rats). The lesions were not confined to one particular structure, but lateral lesions always interrupted most of the medial forebrain bundle bilaterally. Medial lesions always destroyed the posterior hypothalamus and made substantial invasions at least into the dorsomedial hypothalamus and the posterior portion of the ventromedial nucleus.

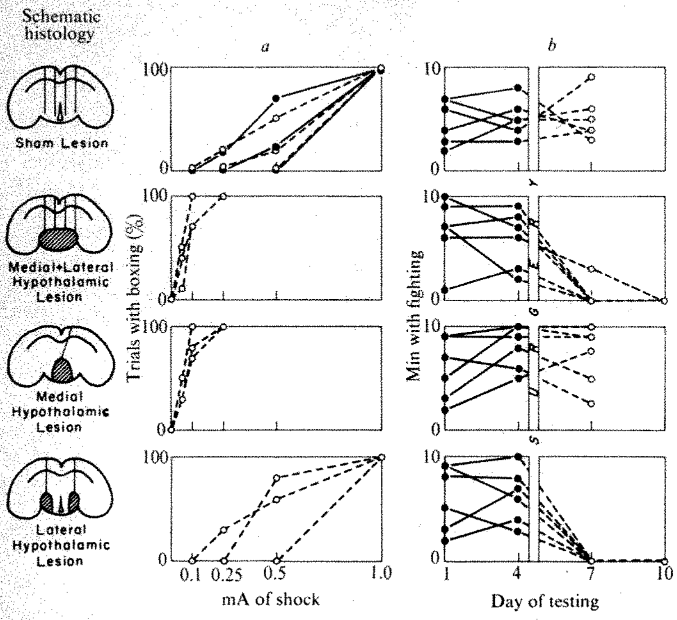

Fig. 1 Effects of hypothalamic lesions in hooded rats on threshold of defence behaviour in the shock box (*a*) and the persistence of territorial behaviour in home cage (*b*). Defence behaviour was defined as defensive upright posture and boxing by both members of pairs of lesioned rats. Territorial fighting was defined as the presence of offensive side posture or full attack posture with biting, and it was quantified by the number of minutes during a test session in which one or the other behaviour was exhibited by the rat in his home cage against an intruder. Pre-operative data were not obtained in the shock box because of an interaction between the shock box and territorial testing procedures. One set of data was obtained from normal animals and is shown on the top line, together with post-operative data from sham-lesion rats. ●—●, Pre-operative testing; ○ - - - ○, post-operative testing.

Lesions involving both lateral and medial hypothalamus on both sides abolished territorial behaviour and simultaneously enhanced defence behaviour in the shock box, both effects being very strong. Rats which had previously attacked an intruder male within 1 min of the intrusion and persisted with biting and offensive side posture for most of the succeeding 10 min were rendered totally docile in the same situation post-operatively. The intruder might sniff at the rat, wander around him, or even lie down on him, but the rat with the lesion would ignore the intruder or sniff at him and turn away. The same animal, on the other hand, would show defence upright posture and boxing in the shock box at thresholds only one-tenth of the intensity of normal thresholds. Whereas normal rats usually fought only during presentation of the shocks, the rats with lesions usually continued to fight after the shock was discontinued and often fought spontaneously between trials.

By confining lesions to the medial and lateral hypothalamus it was possible to separate the two effects. The enhancement of defence behaviour in the shock box was caused by lesions of the medial hypothalamus; a lesion confined to the lateral hypothalamus on both sides had no effect. The abolition of territorial behaviour was caused by lesions of the lateral hypothalamus; a lesion confined to the medial hypothalamus had no effect.

Visual Sensations Produced by Cosmic Ray Muons

IN 1961, D'Arcy and Porter[1] demonstrated that when single cosmic ray muons passed through the eyes of supine, dark-adapted observers, a small proportion produced a detectable visual sensation. The effect was ascribed either to the production of Cherenkov light in the eye media by the relativistic, singly charged particles or to some form of direct stimulation of the retina. Interest in the possible visual effects produced by fast charged particles has revived recently, following reports by the Apollo astronauts that they saw "flashes of light" while in translunar flight; these flashes may have been caused by the action of cosmic ray nuclei on the eyes[2].

We now present the preliminary results of a study which confirms and extends the observations of D'Arcy and Porter. Cosmic ray muons travelling downwards within roughly 15° of the vertical were selected by a counter telescope consisting of one or two 2.5 cm diameter disks of plastic scintillator and a 58 cm diameter tank of liquid scintillator placed approximately 90 cm below. The observers lay with their heads between the scintillators comprising the telescope. Four body positions were used, to allow study of the effects of muons passing in different directions through the eyes and head. For the prone or supine positions two small scintillators were used, placed in close proximity to each eye. Alternatively, the observers lay on their sides with their visual axes horizontal and a single small scintillator positioned close to the head to select muons passing laterally through either both eyes or through the visual cortex. In each position, a muon detected by the counter telescope actuated a scaler and a loudspeaker to give a click audible to the observer. A higher rate of muons was detected by a second control telescope some distance from the observer; this triggered a second scaler and gave an identical click on the loudspeaker. The observer was simply required to state "yes" or "no" according to whether he saw a flash of light of any character occurring in coincidence with a loudspeaker click. His replies were recorded by an operator who also read the scalers and thus knew whether the muons had passed through the "genuine" or "control" telescopes. The experiment thus consisted of determining whether a higher proportion of affirmative responses was given for those muons which passed through the eyes or cortex as compared with those that passed through the control telescope.

Ten observers each underwent four recording sessions in each of the four body positions; a recording session consisted of 30 min of dark-adaptation followed by 30 min of responses. Our observers, like those of D'Arcy and Porter, differed considerably in their ratios of affirmative replies and for brevity we present in Table 1 the summed responses for all the observers, that is for a total of 20 h of actual observation in each position. *P* represents the probability by a χ^2 test that the yes/total ratios for the genuine and control events came from the same population.

Table 1 Responses of Observers

Position	Genuine counts Total	Genuine counts Yes	Genuine counts Yes/total	Control counts Total	Control counts Yes	Control counts Yes/total	P
Prone (face down)	3,878	558	0.144	9,404	1,050	0.112	<0.001
Supine (face up)	4,682	763	0.163	6.421	887	0.138	<0.001
Side (eye)	3,411	487	0.143	6,448	740	0.115	<0.001
Side (cortex)	3,549	456	0.128	6,256	806	0.129	0.94
Supine (D'Arcy and Porter[1])	274	65	0.237	1,613	247	0.153	<0.001

It is clear that, for the three cases when the muons passed through the eye, visual effects were observed; these were absent when the particles passed through the cortex. Although the Cherenkov angle in the eye is quite large (~41°) and the retina extends over rather more than a hemisphere, it would be expected that the coupling to the retinal receptors of Cherenkov light produced by muons travelling parallel to the visual axis and entering the front of the eye would be more efficient than that for similar particles entering from the rear of the eye. The resultant marked improvement in the detection efficiency for the supine over the prone position does not seem to exist. It has been shown[2] that it is unlikely that a singly charged fast particle could produce enough visible Cherenkov light to constitute a supra-threshold signal. Our results therefore seem to favour a direct-excitation phenomenon at the retinal level, probably related to that occurring with X-rays[3] and with knock-on protons produced by fast neutrons[4-6].

The Absolute Configuration and Crystal Structure of the Anticholinergic Drug Dexbenzetimide

THE pharmacological activity of (±) benzetimide (Fig. 1) ((±)-1-benzyl-4-(2,6-dioxo-3-phenyl-3-piperidyl)-piperidine HCl), a potent and persistent anticholinergic agent, acting in both the peripheral and the central nervous system, is due entirely to the (+)-isomer dexbenzetimide[1]. The drug is used to abolish Parkinson symptoms sometimes evoked in psychiatric patients being treated with neuroleptic drugs[2]. The anticholinergic properties are due to the unaltered dexbenzetimide and not to its metabolites[3]. As dexbenzetimide is specifically taken up and retained by small nerve endings of the caudate nucleus of the rat[3], it is tempting to assume that the binding sites are at or near an acetylcholine receptor.

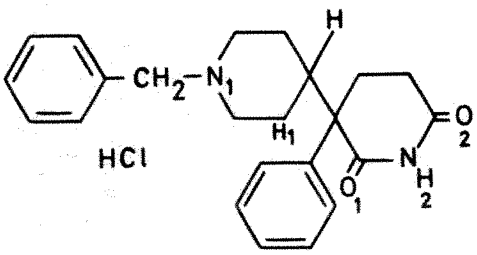

Fig. 1 (±) Benzetimide.

A Stuart–Briegleb model[4,5] of benzetimide indicates that except at the benzyl moiety, the molecule is rigid with a flat hydrophilic bottom and a lipophilic top. A footprint in plaster-of-paris was made of the hydrophilic side of the benzetimide model showing the imprints of N(1), H(1), O(1), H(2) and O(2). A model of the transconformation of acetylcholine, which is thought to be responsible for the muscarinic activity of the molecule[6], fits this footprint perfectly. The footprint was tested with a number of S-B models of optically active

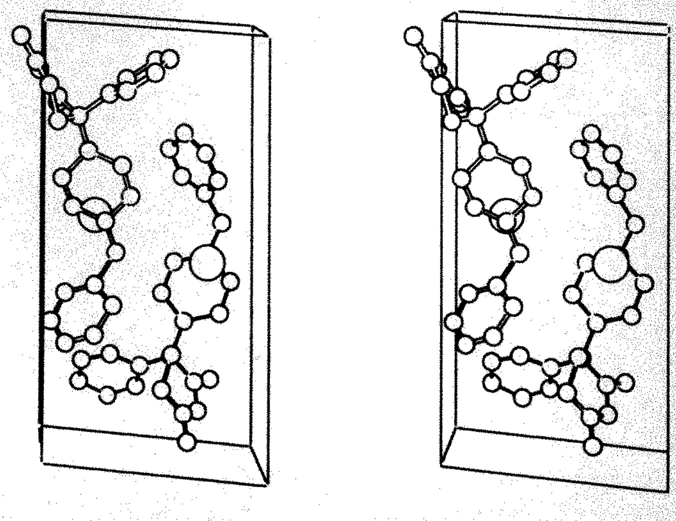

Fig. 2 Stereoscopic plot of the unit cell-content of the dexbenzetimide-HBr crystals. The larger circles represent Br and the small circles represent C, N or O.

agonists and antagonists with known absolute configuration of the pharmacologically active antipode, but only the models of the active antipode fitted the footprint as the acetylcholine model did. This strongly suggests that the model of benzetimide used in making the footprint is the model of the pharmacologically active antipode, which means that this dextrorotating antipode must have the S configuration.

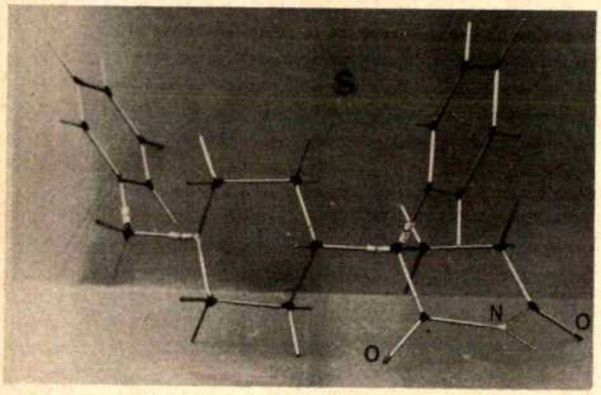

Fig. 3 Dreiding model of dexbenzetimide of one of the conformations in the unit cell.

On the strength of this we predicted the absolute configuration of the pharmacologically active antipode of 1-trimethylammonium-2-acetoxy cyclopropane[4,5] which was confirmed by X-ray diffraction[7]. To justify this method we determined the absolute configuration of (+) benzetimide (dexbenzetimide) by X-ray diffraction. The structure of the tricline crystals of dexbenzetimide-HBr was solved by using a new symbolic phasing procedure, the details of which will be published later (data available on request). The pertinent data are: space group P_1, cell dimensions $a = 7.319$ Å, $b = 9.014$ Å, $c = 17.49$ Å, $\alpha = 94.9°$, $\beta = 99.1°$, $\gamma = 80.3°$, two formula units in the unit cell, 56 non-hydrogen atoms in the cell. The absolute configuration, S as shown in Fig. 2, was determined by anomalous isotropic refinement of both enantiomorphs, using 2,604 reflexions. It resulted in

$$R_2 \equiv \left(\frac{\Sigma(F_0 - F_c)^2}{\Sigma F_0{}^2}\right)^{1/2}$$

values of 18.5% and 18.7% and there is therefore a significant difference between the fit of the observed structure factors and that of the calculated structure factors for each enantiomorph, fixing the absolute configuration to the predicted one, S. A Dreiding model of one of the molecules in the unit cell is shown in Fig. 3.

Fracture of Bone Materials in Compression at Temperatures between −200° C and + 200° C

Recent studies[1,2] of bone materials have suggested that the fracture behaviour is sensitively dependent on specimen orientation, microstructure, the presence of external notches, temperature and the deformation rate imposed. The deformation properties of bone have been likened to those expected of composite materials[2,3]. This report provides further information about the strength of bone and helps to define the criteria which must be satisfied by theoretical models of the mechanical properties.

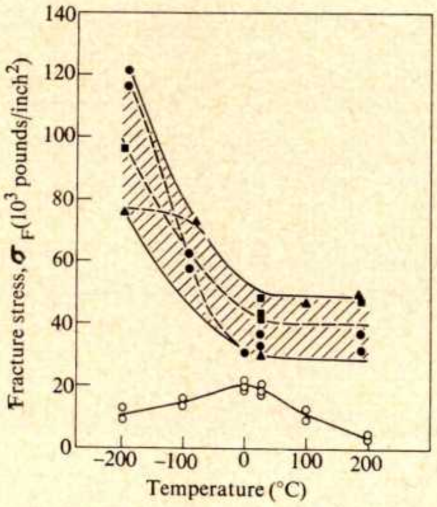

Fig. 1 Compressive and tensile fracture stress of bone at various temperatures. Compression tests: ●, aged, 25° C; ■, as received; ▲, annealed, 110° C. ○, Tensile results of Bonfield and Li[1].

Specimens for compression tests were made from two different bone materials. Ten cylindrical specimens 0.472 cm in diameter and 1.27 cm in height were made from the section of a steer femur which had been thoroughly dried by ageing for 2 yr in normal atmospheric conditions after the immediate removal of the centre marrow. The specimen axes were essentially parallel to the length of the bone. The specimens showed no macroscopic porosity and were machined on a lathe with a maximum layer removal of 0.025 cm per pass. Another set of ten tetragonal specimens 1.01 cm in height and square cross-section of 0.5 cm per side were produced from wet bovine femur material within two weeks of death. Specimen surfaces were ground flat and parallel to within 0.0025 cm by layer removal per pass equal to or less than 0.025 cm. Five of these specimens were annealed in a vacuum of 10^{-5} mm Hg at 110° C for 170 h. The specimens were tested within a specially constructed cylindrical compression chamber mounted on a floor model Instron testing machine so that the entire chamber could be immersed in liquid baths at various temperatures[4]. A strain rate of $\sim 10^{-3}$ s^{-1} was used.

The fracture stresses required at various test temperatures are shown in Fig. 1 along with the tensile fracture stress results of bovine femur material[1]. At room temperature, the measured compressive strengths lie between 29,000 and 48,000 pounds/inch^2. Within this range, the compressive strength does not change appreciably at temperatures above 0° C, but does increase strongly at temperatures below 0° C. The ratio of the fracture stresses in compression and tension varies from 8.0 to 12.0 at the highest and lowest test temperatures. At room temperature the ratio is between 1.5 and 2.5. The upper limiting values of this ratio may be explained on the basis that a single critical flaw governs the fracture strength according to a Griffith energy release hypothesis[5]. The lower limiting value of this ratio may be associated with brittle fracture behaviour in normally ductile polycrystalline materials whereby the yield stress, as measured in compression, is equated to the brittle (cleavage) fracture stress, as measured in tension[6].

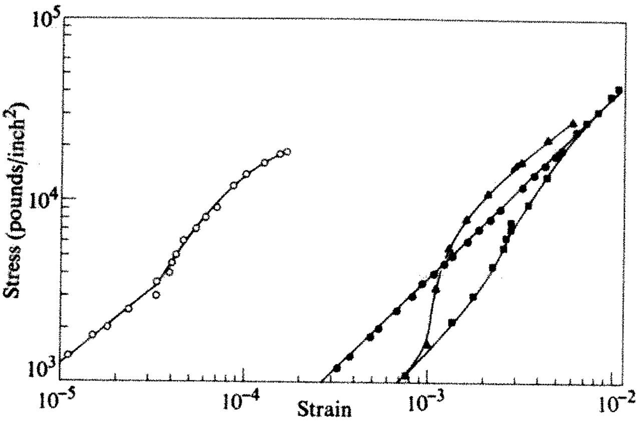

Fig. 2 Stress-strain behaviour of bone in compression or tension at 25° C. ■ and ▲, as in Fig. 1. Tensile results[1]: ○, plastic strain only; ●, total strain.

The compressive stress-strain behaviour of two specimens deformed at room temperature is shown in Fig. 2 versus the tensile stress-strain behaviour previously reported on a similar material[1]. From the original compression specimen, a linear curve was obtained at large strains that was essentially identical to the extended stress-strain behaviour predicted for the tensile specimen, both specimens giving an elastic modulus of 3.8×10^6 pounds/inch^2. But this compression specimen showed a yield point drop and an attendant elastic strain decrease at 7,600 pounds/inch^2. The better fabricated and aligned compression specimen in the annealed condition showed a linear stress-strain behaviour after smaller strains and an increased elastic modulus value of 5.0×10^6 pounds/inch^2, as expected. This comparison indicates that at room temperature the tensile and compressive stress-strain behaviour of bone material is similar except that fracture occurs in tension at smaller strain values.

The results show that the compressive strength of bone at various temperatures shows a distinctive behaviour which, when compared with tensile results on similar material, produces some new conditions to be explained by any theory proposed to encompass the total deformation and fracture behaviour.

We thank Dr S. B. Mohanty for bone materials and Dr W. L. Phillips for assistance with the measurements. This research has been supported by the Advanced Research Projects Agency through the Center of Materials Research and by the Office of Naval Research.

Synthesis of Cystine in Simulated Primitive Conditions

IN an attempt to utilize the very abundant long wavelength ultraviolet solar radiation for prebiological organic chemistry, a series of experiments was performed in which H_2S was introduced as the long wavelength photon acceptor. These experiments are described in detail elsewhere[1], but in a typical experiment a spherical reaction vessel was filled with methane, ethane, ammonia, water vapour and H_2S and the gases were irradiated in cylindrical geometry with the 2537 Å and/or 1849 Å resonance emission lines of mercury. The gases and their photolysis products were then circulated over a liquid water bath by a greaseless solenoid pump and returned to the reaction vessel (Fig. 1).

In one experiment, the initial mixture contained 612 cm^3 of CH_4, 2,024 cm^3 of C_2H_6, 1,004 cm^3 of NH_3, 542 cm^3 of H_2S and 16 cm^3 of liquid H_2O. The mixture was irradiated with 2537 Å radiation for 30 h at a gas temperature which ranged from 215° to 360° C. A deep brown viscid liquid was formed and examined by ion exchange chromatography in a Beckman model 120C amino-acid analyser. The identity of the peak which corresponded to cysteine was confirmed by adding a known standard chromatographically pure solution of cysteine to our brown liquid sample and noting that the appropriate peak increased in amplitude, with no shoulder introduced. The cysteine detected was present at a concentration of approximately 5×10^{-3} µmol/cm^3.

In a second experiment, 591 cm^3 of CH_4, 2,010 cm^3 of C_2H_6, 1,000 cm^3 of NH_3, 549 cm^3 of H_2S and 15 cm^3 of liquid H_2O were introduced into the reaction vessel and irradiated with 2537 Å and 1849 Å radiation for 2 days, with 2537 Å for 1/2 days and again with 2537 Å and 1849 Å for 9 days. The average gas temperature during this 12 day experiment was 400° C. The deep brown viscid liquid solution produced in this experiment was sequestered for 3 months. When examined with a Beckman model 120C amino-acid analyser, cystine was found but no cysteine; the amount of cystine produced was approximately 0.042 µmol/cm^3. The presence of cystine was confirmed by the absence of a shoulder when a cystine standard was performed on a Hitachi model 'KLA-3B' amino-acid analyser (Fig. 2). In this experiment 2 mCi of $^{14}CH_4$ and 1 mCi of $^{14}CH_3{}^{12}CH_3$ were also introduced into the reaction mixture at the beginning of the experiment and the liquid products were examined by two dimensional autoradiographic paper chromatography (Whatman No. 1 paper). The two solvents were 10 methanol : 10 n-butanol : 5 water : 2 ammonia, and 10 acetone : 10 n-butanol : 5 water : 2 ammonia. The chromatograms were then placed against Kodak medical X-ray film NS–54T and developed by a 1 month exposure. A spot corresponding to cystine was found. The presence of cystine in this experiment can be regarded as confirmation of the results of the previous experiment because cysteine has a tendency to oxidize to cystine.

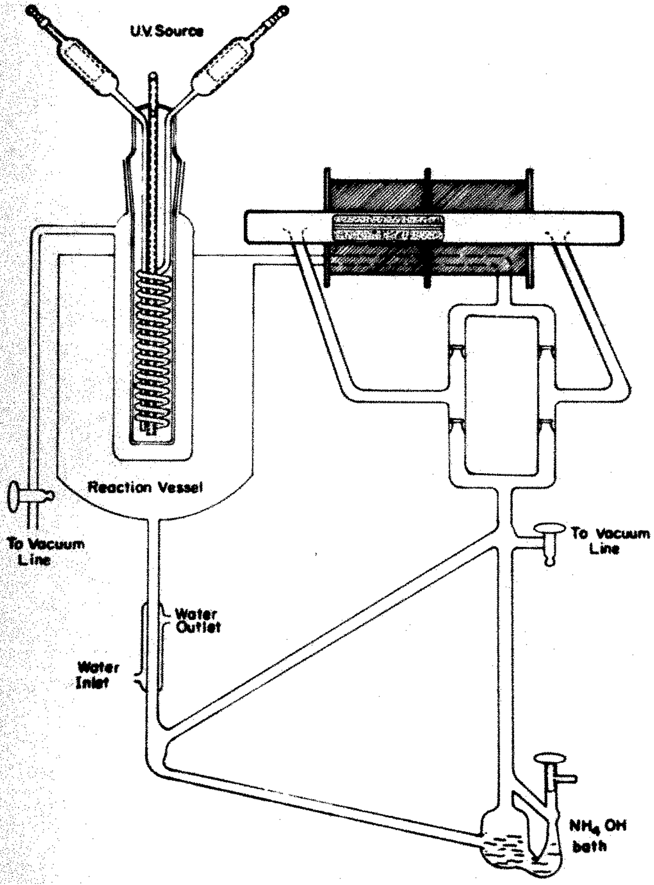

Fig. 1 Schematic diagram of experimental apparatus. Gases irradiated in the reaction vessel are circulated by the Watson pump, upper right, through an ammonia solution (*p*H 12), lower right.

In a third experiment, 1,638 cm^3 of CH_4, 6,055 cm^3 of C_2H_6, 3,035 cm^3 of NH_3, 1,678 cm^3 of H_2S and 50 cm^3 of liquid H_2O were introduced into the reaction vessel and irradiated with 2537 Å radiation for 25 days at a temperature of 50° C. Half of the 50 cm^3 of coloured liquid product was taken from the aqueous bath, dried under nitrogen and hydrolysed for 22 h with 5.7 M HCl. Although no free cystine was found, a trace was detected with the amino-acid analyser in the acid hydrolysate.

In all three experiments, the closely related α-amino-acid serine was also found. Control experiments—in which the gas was heated to 300–400° C for 11 days but not irradiated, or in which the gas was irradiated at 2537 Å at 20° C for 14 h but in the absence of ethane—gave negative results for amino-acids[1]. In all three experiments, we obtained preliminary column chromatographic evidence for the presence of cysteic acid.

In an earlier experiment in which a gaseous mixture of methane, ammonia, water and H_2S was irradiated with 10^9 rads from an electron beam accelerator, cysteic acid, taurine and cystamine were found[2]. And in another, an aqueous solution of ammonium thiocyanate was irradiated with 2537 Å; the sulphur-containing amino-acid methionine was identified by autoradiographic paper chromatography with three different solvent systems. In our experiments we found a spot which appeared to have the position and shape of the methionine paper chromatography spot. A known sample of methionine was run on Whatman No. 1 chromatographic paper, eluted and analysed on an AEI model 'MS–902' mass spectrometer. A similar analysis of the unknown spot gave a mass spectrum quite different to that of methionine. Similarly, the addition of a methionine standard to our solution showed the unknown to be the shoulder of the methionine standard (compare Fig. 2).

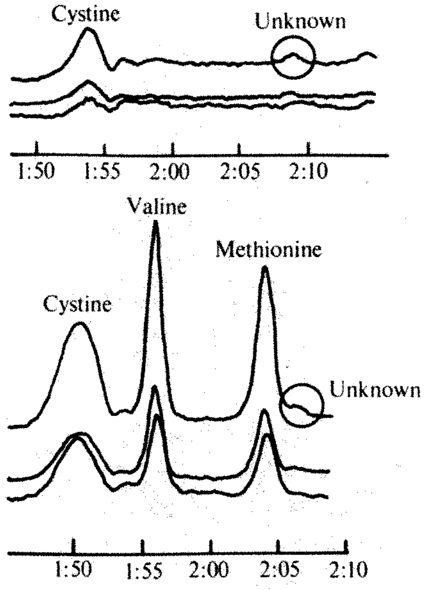

Fig. 2 Ion exchange chromatograms of experimental samples (above) and experimental samples plus chromatographically pure cystine, valine and methionine standards (below) produced by a Hitachi model KLA-3B amino-acid analyser. The coincidence of peaks near elution time 1 : 50 and the non-coincidence near 2 : 07 is evidence for the presence of cystine but not of methionine. The elution time phase shift in the two chromatograms, obtained in slightly different conditions, is expected.

The yield of cystine in our experiments was probably considerably larger than we detected. Both cystine and cysteine are known to decompose readily in alkaline solution to pyruvic acid, H_2S, NH_3 and sulphur[4]. Because NH_3 was present in our system, the conditions in aqueous solution were quite alkaline (*p*H 12). Sulphur polymers up to S_8 were detected by mass spectrometry in the aqueous phase of our system, but these are mostly direct products of H_2S photolysis. The alkaline hydrolysis of cystine regenerates the ammonia and H_2S involved in its photolytic production and leads to a considerable accumulation of pyruvic acid, a substance of particular interest in the context of the Horowitz hypothesis for the reverse evolution of enzymatic reaction chains[5]. Pyruvic acid is the end product of the anaerobic glycolytic pathway ubiquitous in terrestrial organisms. In addition Forbes and Savige[6,7] have found that visible and long wavelength ultraviolet light incident on alkaline or neutral solutions of cystine in the presence of air leads to a rapid conversion of cystine to alaninethiosulphonic acid and alaninethiosulphuric acid, together with smaller amounts of alaninesulphuric acid, cysteic acid, H_2S and two unidentified amino-acids. Thus, because both alkaline hydrolytic and photolytic destruction of cystine are known to occur in our experimental or post-experimental conditions, these experiments suggest a plausible mechanism for the high yield production of cysteine and cystine in the early history of the Earth.

This research was supported by the National Aeronautics and Space Administration, the Smithsonian Institution and the US Public Health Service. We thank Nurit Bar-Nun, Robert Goldberg, Jeremy Hribar, Fred McLafferty, James Bartholomew and Arabinda Guha for assistance and advice.

Cannabivarin and Tetrahydrocannabivarin, Two New Constituents of Hashish

We have identified two more constituents of hashish to add to the constituents of hashish already known[1]. In 1969 Vollner *et al.*[2] identified cannabidivarin, a cannabidiol homologue in which the side chain is C_3H_7 instead of C_5H_{11}. All cannabinoids found until then had contained an olivetyl group (n-amylresorcinol). This was the first cannabinoid found which contained a divarinyl group (*n*-propylresorcinol). Because many constituents are derived from cannabidiol and cannabidiolic acid, Vollner *et al.* predicted that hashish would yield more constituents derived from cannabidivarin, and indeed Gill *et al.*[3] found in 'Tincture of Cannabis' (BPC) a Δ^1-tetrahydrocannabinol homologue with C_3H_7, instead of C_5H_{11} as the side chain.

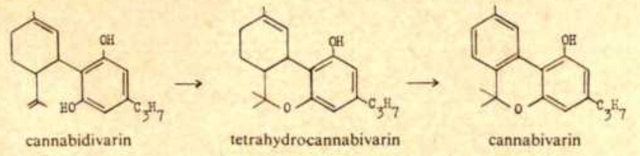

Fig. 1

Using a modification[4-11] of Korte and Sieper's[12] thin-layer chromatographic method we noticed an intense violet spot from a sample of Nepal hashish: the colour was similar to that of the cannabinol spot. We therefore isolated this constituent by preparative thin-layer chromatography and subjected it to mass spectrometry.

The mass spectrum had a molecular ion peak at *m/e* 282 and other peaks at *m/e* 267 (M^+-CH_3, base peak) 239 (M^+-C_2H_4), 238 (M^+-C_2H_5), 223, 209, 195, 165 and 141. From this fragmentation pattern, which is very similar to that of cannabinol[13], it can be concluded that the unknown constituent is a cannabinol homologue, in which the side chain is C_3H_7 instead of C_5H_{11}. We proposed for this constituent the name cannabivarin[14]. This compound can be derived in biogenesis from the tetrahydrocannabinol homologue, and so we searched for this homologue in the same samples of Nepal hashish.

We also found a red spot of unknown origin between the cannabinol spot and that of tetrahydrocannabinol. The red colour was very similar to that of the tetrahydrocannabinol spot. We succeeded in isolating this component by preparative thin-layer chromatography and we elucidated the chemical structure by mass spectrometry. The mass spectrum had a molecular ion peak at *m/e* 286 and peaks at 271 (M^+-CH_3), 243 (M^+-C_3H_7), 203 (base peak), 165. This mass spectrum has the characteristic fragmentation pattern of Δ^1-tetrahydrocannabinol[13], with the difference that all masses are twenty-eight units smaller (the difference between the mass of C_5H_{11} and C_3H_7).

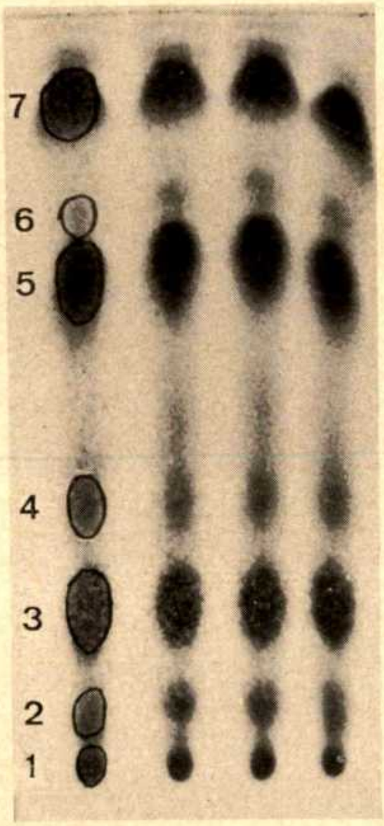

Fig. 2 Thin-layer chromatogram of a sample of Nepal hashish. The sample was extracted with petroleum ether and after evaporation of the petroleum ether the residue was dissolved in chloroform. The separation was carried out on a precoated silica gel plate, impregnated with dimethylformamide and carbon tetrachloride (6+4) and dried in air at room temperature for 30 min. The plate was developed three times with cyclohexane and finally sprayed with 0.5% fast blue salt B in water. The sequence of the separation and the colours of the spots are: (1) cannabidiolic acid (orange); (2) cannabidivarin (orange); (3) cannabidiol (orange); (4) cannabivarin (violet); (5) cannabinol (violet); (6) tetrahydrocannabivarin (red); (7) tetrahydrocannabinol (red).

Thus, the unknown component is a tetrahydrocannabinol homologue, in which the side chain is C_3H_7 instead of C_5H_{11}. We propose for this component the name tetrahydrocannabivarin, according to the names cannabidivarin, proposed by Vollner and coworkers[2], and cannabivarin, proposed by us[14]. Subsequently, we established the identity of a hitherto unidentified orange spot between the starting point and the cannabidiol spot as cannabidivarin.

In all the Nepal samples we studied cannabidiol, tetrahydrocannabinol and cannabinol were also present, and so it seems that two parallel biosynthetic processes are possible in the same cannabis product: cannabidiol (CBD)→tetrahydrocannabinol (THC)→cannabinol (CBN) and cannabidivarin (CBDV)→tetrahydrocannabivarin (THCBV)→cannabivarin (CBV) (Fig. 1).

The sequence of the R_F values of the different constituents can be explained as follows (Fig. 2). The hydrogen bond between the stationary phase dimethylformamide and the phenolic group of the three cannabinoids, containing the propyl group, is stronger than the bond between dimethylformamide and the cannabinoids containing the amyl group. Supposing an equal solubility in the solvent cyclohexane, the R_F values of the three cannabinoids with the propyl group are lower than the R_F values of the corresponding cannabinoids with the amyl group. Indeed the following sequence of R_F values is obtained: cannabidivarin < cannabidiol <, cannabivarin < cannabinol and tetrahydrocannabivarin < tetrahydrocannabinol. The quantitative determination was carried out by gas liquid chromatography on a 'SE 52' column (Fig. 3).

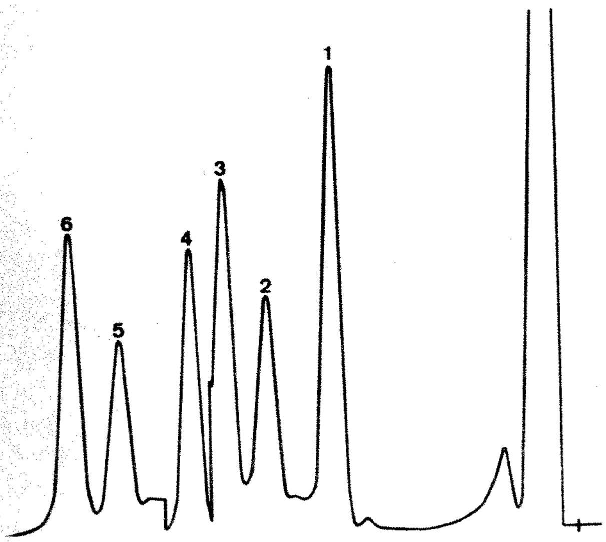

Fig. 3 Gas liquid chromatography of a sample of Nepal hashish. The sample was extracted with petroleum ether and after evaporation of the petroleum ether the residue was dissolved in chloroform. The separation was carried out on a column of 'SE 52' (5% on 'Gas Chrom Q'), column temperature 225°–280° C, 6°/min, N_2 flow 40 ml./min, flame ionization detector. Peak numbering: cannabidivarin (1), tetrahydrocannabivarin (2), cannabivarin (3), cannabidiol (4), tetrahydrocannabinol (5), cannabinol (6).

The retention times of the chief constituents of the samples of Nepal hashish were on the 'SE 52' column (column temperature 225°–280° C, 6°/min, N_2 flow 40 ml./min): cannabidivarin 4 min 19 s, tetrahydrocannabivarin 5 min 29 s, cannabivarin 6 min 12 s, cannabidiol 6 min 48 s, tetrahydrocannabinol 8 min 00 s, and cannabinol 8 min 53 s. The peak areas were measured by height × width at half height. Table 1 summarizes the quantitative determination of three samples of Nepal hashish. The three cannabinoids containing the divarinyl group seem to be present in large quantities in proportion to the other well known cannabinoids. The maximum percentages of the total amount of the six chief constituents we found were 15.8% for cannabivarin, 5.7% for tetrahydrocannabivarin and 12.3% for cannabidivarin. These findings are significant not only for chemistry but also in assessing the biological activity of samples of hashish containing these constituents.

Table 1 Amounts of Single Components in Nepal Hashish as Percentage of Total Cannabinoids: Cannabinol, Tetrahydrocannabinol, Cannabidiol, Cannabivarin, Tetrahydrocannabivarin and Cannabidivarin

	Sample A	Sample B	Sample C
Cannabinol	22.1	24.8	30.3
Tetrahydrocannabinol	11.5	3.4	5.5
Cannabidiol	35.9	41.1	41.2
Cannabivarin	12.5	15.8	11.6
Tetrahydrocannabivarin	5.7	3.0	2.3
Cannabidivarin	12.3	11.9	9.1

The quantitative determination was carried out by measuring the peak areas on a gas chromatogram, made on an 'SE 52' column.

Tetrahydrocannabivarin will undoubtedly have psychotomimetic properties and is a more polar compound than tetrahydrocannabinol. Its biological activity will be smaller, since from earlier studies[15] with synhexyl (a THC-like compound), in which the side chain was varied, it seemed that the activity in the n-alkyl series rises to a maximum at n-hexyl and then falls off again. But we think the more polar character of tetrahydrocannabivarin may influence the resorption, the onset of action, the formation of polar metabolites and the excretion in man.

In relation to this, two recent studies are of interest. Gill *et al.*[3] found that tetrahydrocannabivarin is 4.8 times less active than tetrahydrocannabinol in producing a cataleptic effect in mice. Tetrahydrocannabivarin, however, contributes significantly to the early part of the response of mice to crude cannabis, while tetrahydrocannabinol itself acts very slowly. Second, from the investigations of Lemberger, Silberstein, Axelrod and Kopin[16] it can be concluded that tetrahydrocannabinol persists for many days in normal volunteers and that it is metabolized in man and excreted as polar metabolites in urine and faeces. These observations enable us to conclude that the presence of tetrahydrocannabivarin in a sample of hashish will contribute significantly to the psychotomimetic activity of that sample.

It is also likely that tetrahydrocannabivarin will have an additive or a synergistic effect to the tetrahydrocannabinol effect. We have found that in many samples of hashish a considerable quantity of cannabidivarin, tetrahydrocannabivarin and cannabivarin is present. The identification and the quantitative determination contribute to a more exact chemical knowledge of the constituents and their biosynthesis and allow a better understanding of the different biological activities of hashish samples.

Acid Monoamine Metabolites in Cerebrospinal Fluid during Methadone Maintenance

SOME studies of the interaction of narcotic analgesics and brain monoamine systems have implicated brain monoamines in acute and long term effects of the principal narcotics[1], but interspecies variation makes it difficult to apply these results to man. Techniques are now available which use monoamine metabolites in cerebrospinal fluid (CSF) as indicators of central monoamine metabolism[2–4]. Using measures which reflect central 5-hydroxytryptamine (serotonin) and dopamine synthesis, we studied patients on methadone maintenance therapy for heroin addiction.

Twenty-five determinations were made in sixteen male (ages 25–46) and five female (ages 25–32) heroin addicts who were taking single daily doses of methadone (25–135 mg/day). For ten determinations, 4 ml. CSF was obtained by lumbar tap while a group of subjects was taking methadone only. Before fifteen further determinations, another group of subjects were given probenecid, 3.0 g/day orally for 2.5 days before CSF sampling as described before[5,6]. Probenecid blocks the egress of acid monoamine metabolites from CSF and brain and as a result metabolite concentrations increase[7–9]. Acid monoamine metabolite values in CSF obtained after the use of probenecid may therefore reflect more closely than baseline values the formation rates of the metabolites within the central nervous system. Samples were assayed fluorimetrically for 5-hydroxyindoleacetic acid (5HIAA, acidic metabolite of serotonin) and homovanillic acid (HVA, acidic metabolite of dopamine)[2–4]. Similar non-paired samples with and without probenecid were obtained from a group of psychiatric inpatients (within 10 days of hospital admission, no drugs for at least a week) and from a group of paid inmate volunteers. All subjects gave informed consent. Methadone added to CSF caused no quenching or other interference with acid monoamine metabolite readings except at very high concentrations (1 mg methadone/ml. CSF). In studies involving mice, methadone in substantially larger doses did not interfere with the ability of probenecid to block the egress of acid monoamine metabolites from brain[10].

Unpaired comparisons for 5HIAA and HVA were made between subjects in each category (addicts, psychiatric patients, and inmates) who took probenecid and those who did not. Intergroup comparisons were made for the probenecid and non-probenecid conditions. Addicts in the probenecid condition taking less than 90 mg methadone/day were compared with those taking 90 mg/day or more. Mean values for 5HIAA and HVA were compared by a t test (two tailed).

Without probenecid, compared with inmates, 5HIAA values were significantly lower in the psychiatric and addict groups ($P<0.001$, Table 1). Within the groups, subjects taking probenecid, compared with those not taking probenecid, had higher values for CSF 5HIAA in the case of inmates ($P<0.005$) and psychiatric patients ($P<0.001$), but not in the addict group. On probenecid, the addicts (mean methadone dose 87.4 mg/day) showed a significantly lower value for CSF 5HIAA than inmates ($P<0.001$) and psychiatric patients ($P<0.005$). Without probenecid, the three groups' means did not differ in HVA. Within each group, subjects on probenecid had a higher CSF HVA value than those without probenecid. But the addict group on probenecid showed the lowest HVA value, significantly lower than the psychiatric group ($P<0.01$) but not the inmate group. Addicts taking less than 90 mg of methadone/day as a group had a significantly higher mean value for CSF 5HIAA than those taking 90 mg or more/day. The means (± s.e.) were 40.8 ± 7.3 ng/ml. and 23.8 ± 3.2 ng/ml. respectively ($P<0.05$). Although not significant, the same trend was found for CSF HVA values where the corresponding means were 77.9 ± 10.4 ng/ml. (actual mean methadone dose 66 mg/day) and 52.4 ± 16.2 ng/ml. (actual mean methadone dose 107 mg/day). A daily 90 mg dose is approximately the average maintenance dose in our subjects. Taken altogether, these data indicate that methadone suppressed the formation of 5HIAA and possibly HVA in the central nervous system of the addicts. These results do not differentiate definitely the possible effects on CSF 5HIAA and HVA of addiction to heroin compared with methadone maintenance. But, whatever the effect of heroin addiction, we can say that full maintenance doses of methadone resulted in a greater decrease in CSF 5HIAA and HVA than lower doses. The mechanism underlying this effect cannot be specified at this point, for methadone may be affecting processes of synthesis (including availability of amine precursors) or storage and release in our subjects. Although not the focus of this report, the finding of a decrease in CSF 5HIAA in a psychiatric population is consistent with previous studies[11–13]. The mechanism of this finding is under investigation.

Table 1 Concentrations of 5HIAA and HVA in the Lumbar CSF of Human Subjects with and without Probenecid Pretreatment

Group	5HIAA Without probenecid	5HIAA With probenecid	HVA Without probenecid	HVA With probenecid
I	23.2 ± 2.9 (10)	32.0 ± 4.2 (15)	25.3 ± 7.5 (10)	64.3 ± 10.1 (15)
II	29.6 ± 2.5 (36)	49.9 ± 4.1 (15)	26.0 ± 4.2 (34)	111.5 ± 13.3 (15)
III	43.5 ± 1.7 (18)	59.4 ± 4.6 (20)	23.2 ± 5.9 (17)	86.1 ± 8.2 (16)

Group I are addicts on methadone, group II are psychiatric patients, group III are inmates. Values are ng of the free acid/ml. CSF ± s.e. with numbers of determinations in parentheses. Mean dose of methadone for addicts with and without probenecid was 87.4 and 65.5 mg per day respectively. Mean doses are not significantly different ($P=0.2$).

A number of studies in animals suggest that functional monoamine systems are necessary for both the acute and long term effects of the narcotic analgesics. In the rat, lesions of the midbrain raphe (which destroy the main serotonin neurone group) increased sensitivity to shock and decreased the analgesic effect of morphine[14,15]. Further, reserpine and tetrabenazine antagonized analgesia and tolerance in mice[16,17]. These effects were reversed by 5-hydroxytryptophan and L-dihydroxyphenylalanine, precursors of serotonin and dopamine respectively[14–19]. Monoamine oxidase inhibitors increase the toxicity of narcotic analgesics, probably by increasing levels of serotonin[19]. Further, inhibitors of serotonin and catecholamine synthesis have been reported to increase sensitivity to pain and to antagonize acute and long term narcotic effect[20–22]. These studies, which employ techniques that disrupt monoamine systems, do not explain the effect of narcotics on monoamine turnover, but they suggest that monoamines are utilized in the production of acute and long term narcotic effects. Earlier studies of the effects of narcotics on brain levels of serotonin and noradrenaline showed minimal changes[1]. Some investigators have utilized measurements of monoamine synthesis and turnover. Way and Haubrich found evidence of increased synthesis of serotonin after morphine had been given to mice and rats[23–25]. Others have been unable to reproduce these results[26,27]. We have shown that acute and chronic doses of methadone increased brain 5HIAA in mice[10]. In studies utilizing radioactive tyrosine, Clouet and Ratner reported increased incorporation of radioactivity into both dopamine and noradrenaline after acute and long term treatment of rats with morphine[28]. The results reported here are in contrast with most of the animal data[23–27]. As measured by the formation of acidic monoamine metabolites in CSF, serotonin and probably dopamine synthesis were decreased, at maintenance levels of methadone in our patients. Whether these results reflect a different effect of methadone or narcotics in general on monoamine systems in man compared with other species is still unclear.

While this paper was being reviewed, Tamarkin, Goodwin and Axelrod reported similar findings in three addicts on methadone[29].

This work was supported by a US Public Health Service grant (M. B. B., jun.). Amanda Smith and Angelica Rozitis gave technical assistance.

Life Cycle of *Tripedalia cystophora* Conant (Cubomedusae)

THE Cubomedusae, commonly called "box jellies" or "sea wasps" because of their shape and, for some, their severe sting, are inhabitants of neritic tropical regions of the oceans. Though they have been known for more than 200 yr and the morphology of several species has been investigated[1], little is known of their life histories. Conant[1], in Jamaica, was able to rear the planula of *Tripedalia cystophora* to a four-tentacled polyp. Okada[2], in Japan, reared *Carybdea rastoni* to approximately the same stage. In neither case did the polyps live to an age which revealed their unusual nature. The opinion, held by many zoologists, that the Cubomedusae are an aberrant order of the Class Scyphozoa has therefore derived from a knowledge of the medusa generation alone. This belief, and the view of some authors[3-6] that the polyp is the stem form of all recent Cnidaria, have led to efforts to elucidate the life cycle of a member of this order.

Unlike other Cubomedusae, the fertilized eggs of *Tripedalia* develop into planulae in the gastral pockets of the female medusa. When the planulae are mature, they are released within 2 days. They are then slightly pyriform, have a diameter of 0.13 mm, and contain a yellow-brown pigment. The planulae settle within 2 days. They have a preference for bivalve shells and darkness but will settle on glass or plastic. Two to three days after settlement a polyp with a mouth and four tentacles is formed. Although naked at first, the polyp's base is enveloped by a thin transparent periderm when the four-tentacle stage is achieved. When the polyps begin to feed they grow rapidly.

When 0.5 mm long, with five or six tentacles, the polyps begin to produce asexual buds from the basal body wall. The buds resemble those of *Hydra* and acquire a functional mouth and tentacles before they are released. On detachment, the two to four-tentacled bud or secondary polyp elongates and one of its tentacles becomes much longer than the others. It is capable of gliding, crown first, over the substrate by use of this elongated tentacle. This secondary polyp soon attaches, becomes pyriform, develops a peridermal sheath about the base, and buds off more polyps in the same manner as the primary polyp. At an age of 8–10 weeks the polyps, either primary or secondary, have a single whorl of seven to nine tentacles, a body length of 0.8–1.0 mm, and appear to be fully grown (Fig. 1).

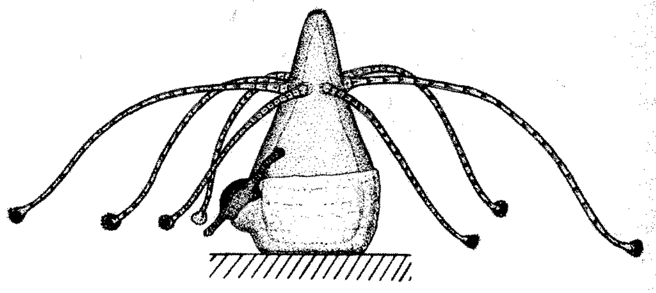

Fig. 1 *Tripedalia cystophora*. Adult polyp; basally, on the left, is a young secondary polyp just before detaching. Length = height of the body is 1.0 mm (drawn by F. Heckmann).

The chief features of the solitary polyp are its long, contractile, cone-shaped peristome and solid, completely retractile, capitate tentacles which bear nematocysts only at their tips. Scyphopolyp features such as a cruciform-shaped mouth, peristomial pits, gastric septa and pockets, septal funnels and muscles, and thick mesogloea are lacking. Only at the time of transformation to a medusa does a tetraradiate symmetry appear. The *Tripedalia* polyp thus more closely resembles a hydropolyp than a scyphopolyp.

The polyp of *Tripedalia* is also unique in that it undergoes metamorphosis into a single medusa. The first evidence of medusa formation is the transformation of the polyp crown to a quadrangular shape. The polyp tentacles then, in no particular order, congregate at the four corners (Fig. 2*A*). The bases of the tentacles, or coalesced bases of several tentacles, thicken and develop small pigment spots (Fig. 2*B*). At the same time, the distal parts of the tentacles are resorbed. Ultimately polyp tentacles, either singly or as a fused group, become the four rhopaloids. Before the polyp tentacles are resorbed, the four primary medusa tentacles appear, *de novo*, between the four rhopaloids. These are hollow, very long, pointed, and are fringed with annular nematocyst batteries. The histology of the developing medusa will be described in a later report, but it can be stated here that the substance of the polyp is completely converted into the tissues of the medusa. At water temperatures of 28°–29° C, metamorphosis to a medusa is completed in 4–5 days. Growth time from planula or newly liberated bud to onset of metamorphosis is 10–12 weeks.

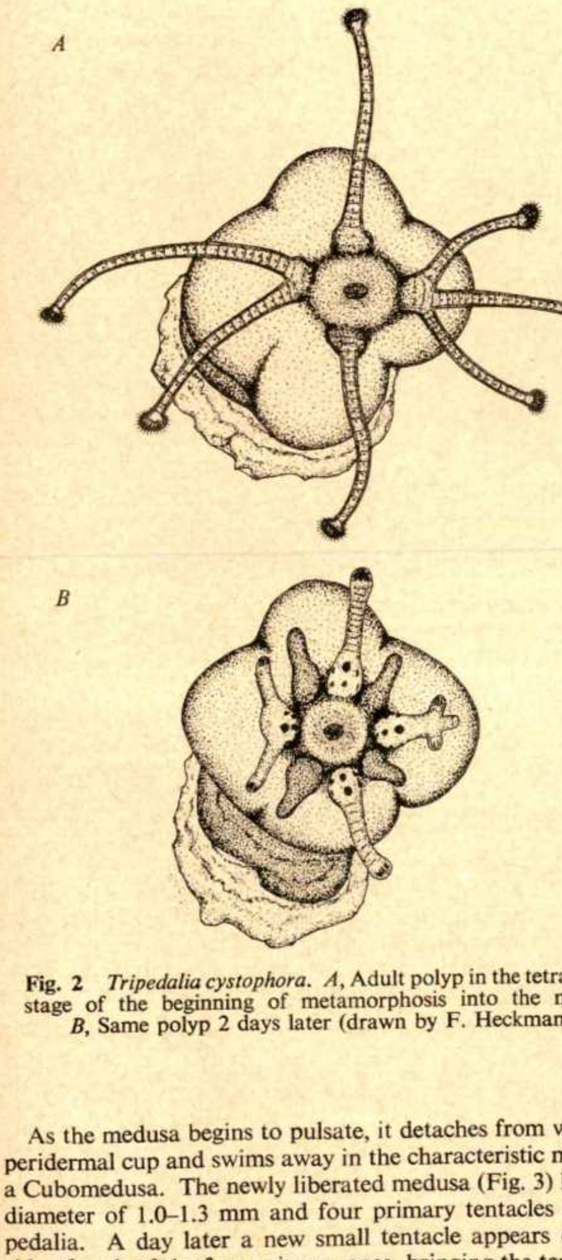

Fig. 2 *Tripedalia cystophora*. *A*, Adult polyp in the tetraradiate stage of the beginning of metamorphosis into the medusa; *B*, Same polyp 2 days later (drawn by F. Heckmann).

As the medusa begins to pulsate, it detaches from within the peridermal cup and swims away in the characteristic manner of a Cubomedusa. The newly liberated medusa (Fig. 3) has a bell diameter of 1.0–1.3 mm and four primary tentacles that lack pedalia. A day later a new small tentacle appears on either side of each of the four primary ones, bringing the tentacles to full complement. Later, the proximal part of each tentacle flattens to become the pedalium. In 10–12 weeks the medusa attains full size and sexual maturity.

Several features of the cubopolyp distinguish it from both a hydropolyp and a scyphopolyp. The more salient of these are the total conversion of the polyp into a medusa, a radial symmetry, and the absence of most of the typical scyphopolyp features. These, together with the morphological peculiarities of the medusa generation, suggest that the Cubomedusae may not be Scyphozoa at all. They possibly may represent an evolutionary link between the Scyphozoa and Hydrozoa and conceivably could be considered to comprise a taxon of comparable rank.

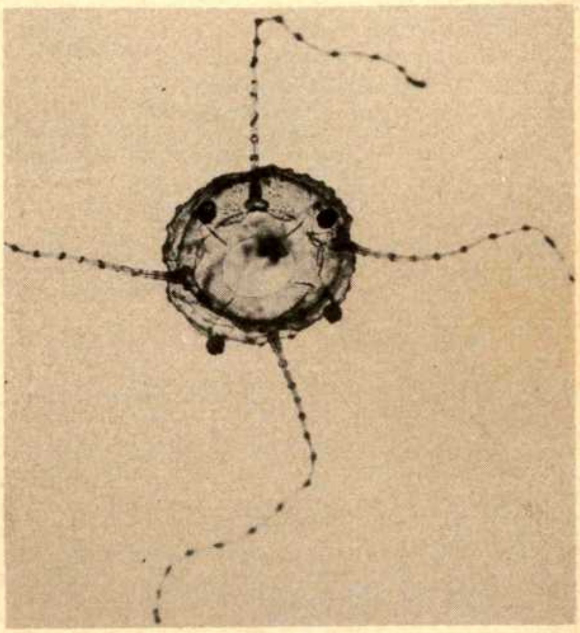

Fig. 3 *Tripedalia cystophora*. Young medusa just after metamorphosis from polyp, reared in laboratory; bell margin above; diameter of the bell is 1.3 mm (photograph by B. Werner).

This study was conducted at the Biologische Anstalt Helgoland and the Department of Marine Sciences, University of Puerto Rico, Mayagüez. BOOK REVIEWS

Science and Society

Science, Man and Society. By Robert B. Fischer. Pp. viii+124. (Saunders: Philadelphia, London and Toronto, March 1971.) £1.25.

The Scientist's Role in Society : a Comparative Study. By Joseph Ben-David. Pp. xi+207. (Prentice-Hall: Englewood Cliffs, New Jersey, June 1971.) $6.95 cloth ; $2.95 paper.

DR FISCHER observes that traditional science courses are organized around particular parts of the subject matter of science. They do not give insight into the relevancy of science to man and to society, when people have to face serious social and political issues in which science is a major factor.

Various approaches are being tried to remedy this situation. One is for the science faculties to turn the problem over to the faculties of philosophy and history. Dr Fischer dismisses this as "passing the buck", as it usually turns out to be no solution. Courses in science may be replaced with courses about science. He thinks this is liable to leave the student with no clear grasp of any important principle. Nor is he in favour of organizing science teaching around topical themes such as pollution: these are subject to fashion. His book contains the selection which he considers suitable.

He stresses that science is a dynamic, human activity, limited to things accessible to the senses. He warns against non-dynamic words such as "systematic" and "organized". The understanding of concepts is gained from experience, and, as Einstein says, "the whole of science is nothing more than a refinement of everyday thinking".

Dr Fischer quotes briefly sketches of Priestley, Cavendish and Faraday as contrasting scientific types. Then he compares the scientists of today with those of two centuries ago. They have more to learn, and even then are deeply acquainted with only a limited field. The long training uniformalizes their knowledge and habits, to fit them for niches in the vast modern scientific activity.

He relates the present crisis in universities to the growth of science. The universities have become a complex of competing subjects and factions, described by Clark Kerr as the "multiversity", in contrast to the ancient "university". Some of the courses, intended to deepen students' general understanding of science, have increased their alienation. The more they know about science, the less they like it. Man has got to the Moon, but not solved the problems of poverty and crime.

It is essential to emphasize that science is subject to man, who is a thinking, feeling, doing being. It is up to man to decide whether science shall be allowed to have dehumanizing effects.

Dr Fischer has written a wise and useful little book which should be helpful to many students, and their teachers.

What help is provided by Dr Ben-David's sociological monograph? He discusses the development of science especially in Britain, France, Germany and the United States. He says that "social conditions do not generate intellectual ability and moral responsibility, they only provide the conditions for their exercise". Accordingly, he interprets the foundation of modern science in seventeenth century Britain as due to people who found empirical natural science "a cognitive structure consistent with their interests in a changing, pluralistic and future-oriented society". The conceptual development of empirical natural science was, he says, quite independent of social circumstances.

In the society of twentieth century United States, the "enterprising system of universities working within a pluralistic, educational, and economic system has created an unprecedentedly widespread demand for knowledge and research and has turned science into an important economic resource". This system has encouraged scientific creativity for its own sake by creating a very wide foundation for pure research. However, the system is in a state of delicate balance between scientific and scholarly creativity and the demands of the economic and political powers. This balance is more delicate than elsewhere because "the pluralistic entrepreneurial structure and expansive system of science and higher education require a much greater involvement of the universities in the affairs of society. This is the price paid for the greater support of science and scholarship". A large section of American youth now receives university education in science. Consequently, "in spite of the greater decentralization of political and economic life", US universities have become "one of the most suitable centres of political activism".

Dr Ben-David believes that there was a comparative decline in British science in the second half of the eighteenth century. It is true that Newtonian science declined, but he does not see that that was already no longer in the first line. The industrial revolution posed new problems, symbolized by the steam engine and the concept of energy, which led to modern physics. Science in Britain changed its direction, founding the line of the future. In France Lagrange and Laplace carried Newtonian science to its apogee, but they were completing old science rather than founding new. If the theory of gravitation is the scientific apotheosis of the British mercantile civilization, the theory of energy is that of the industrial revolution. Ben-David does not perceive in these major social movements examples of the prime forces which have created science.

He comments on the intellectual freedom in German universities in the nineteenth century, while they were the media for nationalistic and anti-semitic propaganda. He says: "it is difficult to determine with any certainty the reason that so many of the 'liberal' elements accepted this situation". Then, he remarks that in the early 1930s "the visiting scientists saw the German university in the light of its ideal self: as a seat of the purest learning for its own sake and an unequalled centre of overall excellence".

In fact, as a visitor to Germany at that period, I was painfully struck by the gap between the high Berlin scientific life and the brutalities done to and by the rank-and-file population. The reason why German scientists put up such a poor show against both German imperialism in the nineteenth century and Nazism in the twentieth was that they had a false philosophy. They believed that "science" was a thing in itself, an affair of the "scientific community", an exalted intellectual endeavour, above the vulgarity of common affairs. Dr Ben-David's book illustrates why "passing the buck" to the sociologists also provides no solution of the problem of science, man and society.

J. G. CROWTHER

Objective Sense

Rationality. Edited by Bryan R. Wilson. (Key Concepts in the Social Sciences.) Pp. xviii+275. (Blackwell: Oxford, November 1970.) £2.75.

ALTHOUGH this collection will particularly interest investigators who regard human actions or utterances as a necessary part of their data, those with a general interest in the nature and scope of scientific thought should also find it rewarding. The contributions represent a coherent tradition of inquiry in areas too abstract and complex for easy intelligibility, but lucid writing, with a minimum of esoteric terminology, comes close to eliminating the difficulties involved.

The central issue is how social scientists should formulate a general strategy for understanding and explaining human beliefs and actions. Such a strategy, it is agreed, must take account of the subjective, meaning which distinguishes "action" from "behaviour". Compare a human being seeking money with a rat seeking food. The desire for money becomes intelligible only through its meaning—its subjective significance in a wide range of social relationships. So for beliefs and actions in general; they can be understood only contextually, as elements in meaningful systems; particular beliefs are intelligible only in so far as the total context of belief is intelligible.

This raises important problems concerning the degree to which mutual understanding is possible between any set of actors. It is in the work of social anthropologists, however, that these problems emerge with particular clarity, and the understanding of alien cultures consequently provides the principal subject of discussion here. How can we know when the meaning of an alien utterance has been captured in our own language? To what extent can the properties of alien belief systems be assumed to resemble our own? And what is to be made of beliefs which seem to us self-evidently false, contradictory or otherwise irrational?

With respect to this last question, two basic positions can be identified. One accepts the existence of "irrationality" and seeks to account for it as such: it is the product of bias, or of a mistaken world view, or illogicality: it persists in a culture because social norms discourage rational criticism, or because scientific method is not available to refute it. The other holds that seeming irrationality can become intelligible if its relationship to its context is more closely scrutinized: if beliefs are given significance only in relation to those actions with which they are concretely associated, their "irrationality" may disappear or become irrelevant: if contextual evidence can make a metaphorical or symbolic interpretation of beliefs plausible then, again, all is well.

The intensity of this conflict unfortunately obscures the fact that the two positions are not mutually exclusive. Irrational or false beliefs, as here defined, are endemic in all societies, and it is hard to apply symbolic explanations everywhere (consider, for example, the "irrationality" which these authors painstakingly demonstrate in each other's work). On the other hand, to interpret the Nuer belief that human twins are birds as symbolism is at least more promising than to treat it as a curious empirical error. Moreover, it is not difficult to combine the approaches: given that there are many ways of being "irrational", symbolism can help to explain why particular examples occur in particular contexts.

Both approaches assume that "irrational" beliefs need different explanatory treatment to "rational" ones, and hence that it is, in principle, possible to distinguish the two by external objective standards. But, in spite of its title, the book does not give this topic detailed consideration; "irrationality" is usually the starting point for analysis, not its product. Crude models of rationality, usually drawn from the philosophy of science, serve as a sketchy backdrop to the problems already discussed. Empiricism lies behind puzzlement at the incidence of false beliefs. Popper's philosophy is linked with interest in why alien actors hold beliefs uncritically. (Unfortunately, P. Winch relates his "all is rational" view of alien belief systems not to T. S. Kuhn but to their common precursor Wittgenstein, thus spoiling the pattern!)

What does emerge is that if objective criteria of rationality exist there is at present no hope of a consensus on what they are. It could in any case be argued, against the dominant approach in this volume, that such criteria are of little interest to the practical investigator. If he must account for the existence of "false" beliefs, he must do no less for "true" ones; if dogmatic adherence to beliefs is problematic, so too is open-mindedness and provisional commitment. Much of the discussion in this volume could be reformulated to apply to the aetiology and ecology of all beliefs, and merely loses perspective by being confined to the analysis of "irrational" residues. Robin Horton's admirable comparison of African traditional thought with that of Western natural science demonstrates the value of widening the scope of the debate, treating our own beliefs with genuine curiosity.

I would agree that any paradigm of rationality must be broadly compatible with the procedures of the natural sciences. Given the rich variety of scientific thought, however, and the way it consistently eludes any single formal description, I am led to adopt what Gellner would call a "charitable" view of alien belief systems, based on the weakest possible rationality criteria. Those who would use stronger or more objective ones should consider, among other things, how much of modern science they would thereby define as irrational. This position comes closest to that of Winch, who nevertheless misuses his own arguments. By treating all belief systems as rational, he does not show that beliefs are immune to causal explanation, but that the same forms of causal analysis can be universally applied to all beliefs—something not yet fully recognized, at least within the social sciences.

S. B. BARNES

Natural Selection

Coefficients of Natural Selection. By L. M. Cook. (Biological Sciences.) Pp. 207. (Hutchinson University Library: London, February 1971.) £2.50 boards; £1.25 paper.

THE problem of explaining mathematical arguments to biologists has driven many a promising teacher to despair. The biological undergraduate, and occasionally even the graduate, is prone to go into shock when faced with an algebraic equation as complex as $a = \frac{bc}{d}$. Nowhere is the problem more acute than in population genetics, where the underlying arguments are largely mathematical but the observations and experiments are firmly based in natural history. Dr Cook has attempted the dreadful task of bridging the chasm between them, and he has largely succeeded.

His book is neither a text for undergraduates, although there are many who would benefit from it, nor an account of methods in research. It is a stimulating, original and idiosyncratic assay about the genetic analysis of natural and experimental populations. He leads his readers gently through the complexities of selection differentials, the calculation of equilibria, and the analysis of selective forces depending on gene-frequency and population density. At times, understandably, he falls into the trap of rendering an argument more obscure by explaining it too much. Less often, but more seriously, the reader may be led astray by misprints (as on pages 29, 43 and 44) or other errors (as on pages 59, 142 and 160). There are some surprising gaps. For example, he chooses to discuss the phenomena of non-random mating without mentioning the work of Ehrman or Spiess.

These are matters, however, that can be remedied if, as devoutly we may wish, the book reaches a second edition. Its virtues far outweigh its vices. An example of these virtues, to a statistically naive reviewer, is a uniquely lucid exposition of the method of maximum likelihood.

I believe that the value of the book will prove to be inversely proportional to the mathematical ability of the reader. It should be welcomed by biologists and neglected by mathematicians.

BRYAN CLARKE

Food and Safety

Metabolic Aspects of Food Safety. Edited by Francis Roe. Pp. xxiii+612. (Blackwell: Oxford and Edinburgh, 1970.) £7.

ABOUT ten years ago the Nuffield Foundation became concerned with the toxicological risks associated with the increase in chemical and physical treatment of food. To evaluate the hazards involved it is necessary to work with small laboratory animals, but lack of knowledge of their diseases made the investigations difficult. In 1966 the first food safety conference lead to the publication of a useful book, The *Pathology of Small Laboratory Animals.* In 1969 the second food safety conference considered the tests used to assess the safey of food additives and contaminants, and the problems that arise in interpretation of experimental results. It is not as easy as might be supposed to decide whether a compound is toxic to an animal even in the conditions of the experiment, without the additional problem of extrapolation to a human population and the conditions in which the compound is or could be consumed. As toxicology is studied by physiologists, biochemists and electron microscopists, there was a need for different people concerned to meet to discuss the problems. The book of the conference is disappointing, although it should be of some use to those engaged in this work.

"Metabolic Aspects" is a very misleading title, as the book is not concerned chiefly with the metabolism of food constituents, additives or contaminants, or with their effects on metabolism of the animal. "Biological Aspects" would have been more appropriate. A very heterogenous collection of twenty articles discusses basic physiology of the small intestine and of gastrointestinal absorption, renal function tests in animals and in man, and the significance of such factors as gut flora, age, sex, hormones and nutritional status of the experimental animal. The fact that protein deficiency makes animals less sensitive to compounds such as heptachlor which exert their toxic effects after metabolism, and more sensitive to compounds such as aflatoxin, the toxicity of which probably does not depend on their metabolic conversion, underlines the difficulty of applying results both to the affluent society and to the undernourished countries.

One basic problem is whether any effect produced by a chemical should be regarded as evidence of toxicity, even if it does not apparently inconvenience the animal. Thus many food additives cause an increase in liver weight, and the problem of whether this is harmful or possibly even beneficial is discussed. Obviously to assess the significance of the increase in liver weight caused by chemicals it should be compared with changes occurring naturally. However, in the present context, the long detailed discussion of the increase in liver weight occurring during pregnancy and lactation seems out of place, in the absence of sufficient comparison with chemically induced enlargement. Only a shrewd question in the discussion brought out a fundamental difference: chemical-induced liver enlargement is frequently accompanied by hypertrophy of the smooth endoplasmic reticulum, that occurring during reproduction is not. The important question of the reversibility of natural and chemically induced changes is barely mentioned. The problem of whether an increase in weight is harmful leads to the question of what controls liver weight, and of the mechanism by which the changes are brought about. Thus it is essential "to find out not only what happened but how it happened" and to study the basic biochemical processes before the results of toxicity tests can be evaluated. Two good chapters get to grips with the problem in this way. One discusses metabolic aspects of liver tumour induction in animals by compounds known or suspected to be food contaminants, and the other discusses the ultrastructural changes.

Although apparently the aim of the book is to have a wide scope rather than to study any particular problem in depth, there are some important omissions. There is no mention of possible hazards to the brain, although the vulnerability of the central nervous system had been demonstrated spectacularly and tragically ten years before, when methyl-mercury contamination of fish was shown to be responsible for Minamata disease in Japan. More surprisingly teratogenesis is not discussed, although dyes, fungal metabolites and other possible food contaminants are known teratogens. The basic physiology, biochemistry and tests of kidney and liver function in man, are dealt with in standard textbooks. If these subjects could have been replaced by discussion more directly relevant in the present context, the book could have gone much further into the problems and would have been a more valuable contribution to the subject.

V. M. CRADDOCK

Tsetse and Ecology

The Role of the Trypanosomiases in African Ecology: a Study of the Tsetse Fly Problem. By John Ford. Pp. xiv+568. (Clarendon: Oxford; Oxford University: London, March 1971.) £6.50.

THE change of title of the East African Tsetse and Trypanosomiasis Research and Reclamation Organization (EATTRRO) to East African Trypanosomiasis Research Organization (EATRO) in 1956 signified a change of approach—from one in which the prime emphasis was on the insect vectors of trypanosomiasis—*Glossina* (tsetse flies)—to a more balanced one in which medical, veterinary, entomological and ecological aspects were to be studied as a whole. Also, the first organization was concerned with both research and reclamation, the second solely with research. John Ford served for many years with the earlier organization, only briefly with EATRO, as director, until he went to Rhodesia as director of tsetse control in 1957. He is primarily an entomologist, but a very thoughtful one, and his book is a fine attempt to put *Glossina* in proportion among the many other ecological factors which affect the African scene. This is a very different approach from that of the generality of British glossinologists, which was that the elimination of *Glossina* was a certain way of controlling trypanosomiasis; that this should be stressed to the near exclusion of all other approaches; and that economical control consistent with the poverty of the African territories affected should be able to be attained by minor interference with the *Glossina* vegetational environments—if only the ecology of these flies were sufficiently understood.

After extended experience of this approach in East Africa, Ford worked in Rhodesia where game elimination as a *Glossina* control measure had been particularly practised. He subsequently visited and studied in West Africa. He has, therefore, a unique first hand acquaintanceship with three different African regions, all sharply affected by trypanosomiasis, but in different ways. The description of trypanosomiasis situations in these three regions form the core of the book. After five introductory chapters giving essential basic information about the organisms concerned—trypanosomes, *Glossina,* animals and man—Ford devotes nineteen chapters to describing five sample areas, three in East Africa and one each in Rhodesia and in Nigeria. He ends with two summarizing chapters, one considering trypanosomiasis in its continental ecological aspects, the other proposing a new approach.

Basically, Ford's thesis is that, before the advent of the Europeans in Africa, the indigenous peoples had made very considerable advances towards overcoming the obstacle of trypanosomiasis by physiological and cultural adjustments in themselves and in their domestic stock and that this fact is usually overlooked. He considers the epidemics of trypanosomiasis in man and animals since the turn of the century to be direct results of the political and ecological aspects consequent on

European colonization, which acted particularly by disturbing the uninhabited no man's land (Grenzwildnisse) which separated tribal areas and kingdoms and which provided mechanisms for adjustment between different tribal groups and with their environment.

Ford marshals an impressive amount of information to support his thesis, delineating the development of affairs in all his five areas. The reader new to the field may find the diversity of the material bewildering, including, as it does, geology, palaeontology, historical fragments, excerpts from the diaries of early travellers, oral tradition, geographical description, entomology, and human and animal demography, all developed together with great profusion of detail so that any individual body of data is difficult to isolate, examine and assess. Nevertheless, the result is of great interest and, whether one agrees or not with Ford's thesis, the book will always be valuable, if only for the amount of data, otherwise difficult to obtain, amassed within it.

In his final chapter, Ford is apprehensive of epidemiological upsets at the termination of the colonial empires as profound as those which attended their establishment and cites present indications from the Congo and the Sudan. He emphasizes, again, the need to relate disease control to expected economic growth rate. He urges the development of the mathematical epidemiology of trypanosomiasis. He laments the neglect of entomologists to study, at the same time as the habits of their insects, also the habits of the people and the animals bitten. He hopes for a better balance under political freedom than has happened under colonial rule. This is questionable and indeed, under the more general approach to trypanosomiasis study in recent years, this lack has been realized and much done to repair it. To my mind, however, much of the uncertainty and misapprehension in the field of trypanosomiasis does indeed derive from the paucity of integrated studies. Trypanosomiasis contrasts sharply in this respect with some other tropical diseases, such as yellow fever, in which integrated teams fairly rapidly worked out the main essentials of the epidemiology, in both South America and Africa.

Considerable progress in integrated studies was indeed made by the East African Trypanosomiasis Research Organization and is indeed still continuing in spite of the dislocation caused by the loss of long-experienced personnel consequent on the granting of independence to East African territories in 1962–63.

The book is well illustrated with line diagrams and is fully indexed. There is a bibliography of some 600 sources.

W. H. R. LUMSDEN

Molecular Pharmacology

Essentials of Molecular Pharmacology: Background for Drug Design. By Andrejus Korolkovas. Pp. xv+339. (Wiley Interscience: New York and London, November 1970.) 160*s.*

THE term molecular pharmacology is of recent currency but may be taken to indicate a new determination among pharmacologists to account for the nature and specificity of drug action in terms of a detailed description of events at the atomic level. Speculation at this level has of course been rife for years but hard facts have been few, and it is really the arrival of new techniques, notably X-ray crystallography of proteins, that have given a great new impetus to this challenging subject. This book deals with the major areas of activity so far including adequate accounts of intermolecular forces and the analysis of chirality. The account of drug–receptor interactions is imaginative and stimulating, but it is here that the weaknesses in contemporary pharmacological arguments become so clear—the argument is based on analogy with enzyme–substrate interactions (themselves not understood unequivocally), and extrapolations from structure activity studies.

The position is rapidly developing where drug binding directly to receptors is possible so that the analogies may be put aside, but as the X-ray studies of binding of enantiomeric glycosides to lysozyme, and isomeric nucleotides to ribonuclease have shown, changes in structure of the ligand may entail a major change in the geometry of the complex that cannot be predicted from structure activity studies. The implication is that structural techniques, particularly X-ray crystallography and nuclear magnetic resonance, must be decisive tools for the molecular pharmacologist.

The theories of drug action discussed in this book are bound to become rapidly clarified as the study of isolated receptors proceeds. It is interesting to see how history repeats itself. The isolation and crystallization of enzymes was inhibited by vitalistic concepts, the isolation of receptors was similarly inhibited by beliefs that receptors could not survive isolation from their environment in membranes; lo and behold, when isolated they are as tough as old boots. Nevertheless, we must not be carried away by excessive optimism, isolation of receptors will not answer all the questions of drug action any more than isolation of enzymes solves the problem of how enzymes work, but it does have the enormous advantage of replacing mystery by tangibility.

For the rapid development of molecular pharmacology that is now just beginning, this book provides a useful and interesting primer that can be strongly recommended.

A. S. V. BURGEN

Complex Chemistry

Organometallic Chemistry. Edited by F. G. A. Stone and M. I. Bruce. (Plenary Lectures at the Fourth International Conference on Organometallic Chemistry, held at Bristol, UK, July 28–August 1, 1969.) (International Union of Pure and Applied Chemistry in conjunction with the Chemical Society, London. *Pure and Applied Chemistry,* Vol. 23, No. 4, 1970.) Pp. 375–503. (Butterworth: London, 1970.) £3.50.

PUBLICATION, in a hard-cover version, of the proceedings of symposia of the Internation Union of Pure and Applied Chemistry has complemented, for the past few years, their normal appearance in the journal *Pure and Applied Chemistry.* One would not have guessed that such a double-barrelled approach would have been profitable for the publishers—it must be a tribute to the balance and high quality of reviews which appear in this volume and in its predecessors.

So far, the only characterized organometallic complex occurring in nature is vitamin B_{12}, and its chemistry is better understood now through the systematic studies of metal complexes of porphins, corrins and corroles. These are reviewed by A. W. Johnson. K. Schlögl concentrates his attention on chirality in the metallocenes and the summary serves as a general reminder that the optical activities of organometallic catalysts and stereospecificity of polymerization reactions could be a renewed focus of interest in the near future. Gubin surveys the information which electrochemical methods have given on energy levels and bonding in the metallocenes and cyclopentadienyl metal carbonyls and Chini completes our exposure to transition metal chemistry by a succinct summary of the chemistry of a number of carbonyl clusters of the iron and cobalt triads.

It is good to see main group organometallic chemistry so well represented. Brown gives a particularly nice account of nuclear magnetic resonance studies of structure and exchange reactions of organolithium compounds; Seyferth summarizes insertion reactions of methylene bridges into group IV hydrides and halides while Neumann emphasizes the free radical chemistry of organotin compounds.

Obviously, individual volumes can have no claim to comprehensiveness but together they represent a most valuable addition to the secondary literature.

CORRESPONDENCE

Metric Chains

SIR,—You chose an unfortunate subject for your aside upon shortening cricket pitches “. . .(. . . a non-metric measure—who now knows what a chain is?)”[1].

It is unfortunate that, with the impending change to the metric system, we do not much use chains and furlongs and even the infamous rod, pole or perch, for they correspond respectively to 20 m, 200 m and 5 m with an accuracy of 0.6%.

Yours faithfully,

S. D. STEEL

Department of Inorganic,
Physical and Industrial Chemistry,
Donnan Laboratories,
Grove Street,
PO Box 147,
*Liverpool L*69 3*BX*

[1] *Nature*, **232**, 433 (1971).

Telescope Administration

SIR,—Twice each year your advertisement pages invite applications for observing time on the Isaac Newton Telescope. Lest any potential applicant be deterred by the “widespread feeling” noted in your editorial (*Nature*, **232**, 289; 1971) that the Royal Greenwich Observatory exerts a detrimental influence on the running of this telescope, perhaps you would allow an informed comment.

If “running” refers to the day-to-day management and maintenance of the telescope, then indeed any neglect here would, as stated, be inimical to the progress of British astronomy. But if this is what is alleged, the proper place to complain is on the spot at the time. No such complaints are in fact made by visiting observers, and those responsible for the care of the telescope must be forgiven if they decline to notice anonymous allegations by others, especially when they are wholly unsupported by facts.

If, however, the criticism is now, as it has been in the past, of the observatory's alleged monopoly in the design and construction of ancillary equipment, it is time to reiterate that no such monopoly exists. Any successful applicant for observing time may bring his own equipment—many of them do—and the only requirement is that it shall be compatible with the telescope itself. As to the larger spectrographs, it is true that these are of RGO design. It is equally true that had the Astronomer Royal not taken the initiative to get them built, no spectrographs for common use would now exist. It is this situation that would indeed have been inimical to the progress of British astronomy.

But maybe the rub lies in the allocation of observing time. This is done twice a year by a Science Research Council panel of six working astronomers, not all of them in the optical field and only one from the Royal Greenwich Observatory. Selection among the applications received is strictly according to the scientific merit of the programmes proposed, and I am sure the members of the panel would repudiate any suggestion that they unduly favour RGO applicants. It is true that RGO applications are in fact awarded more time than any others; but they are in a substantial majority and the panel plainly adjudges them more worthy of support.

If there are those who find the basis of allocation unfair, let them suggest a more equitable one. If they allege sinister influences by the major applicants on the process of allocation, let them produce something more substantial than hints in the scientific press.

Yours faithfully,

A. HUNTER

Secretary, Large Telescope Users' Panel,
Royal Greenwich Observatory,
Herstmonceux Castle,
Hailsham, Sussex

SIR,—Your article on “New Astronomy” (*Nature*, **232**, 289; 1971) was informative and interesting. Before commenting on points of substance, however, may I correct one misunderstanding which the article revealed ?

I refer to the “widely held” criticism, attributed to “many astronomers” who see the RGO as a “white elephant”—on the grounds, according to you, that the £1.2 million which the SRC spends on the RGO, the Royal Observatory Edinburgh and on the observatories in South Africa, gives poor returns compared with the running costs of the Hale Observatories of $1.7 million a year.

The Hale Observatories are not government observatories and have no national responsibilities. They spend nothing on the equivalent of the Nautical Almanac Office, the Time Service and the Meridian and Astrometry Departments of RGO which take up some 57% of the total RGO budget. If you then compare the remaining 43% of the RGO budget, plus the full cost of the South African Observatories and the Royal Observatory Edinburgh, the total comes out for all practical purposes the same as the cost of the Hale Observatories—in round figures, £700,000.

You were, of course, right to draw attention to the disquiet of the scientific staff of the RGO about the future of their scientific work. In part, the bad staff relations in the Science Research Council are a cause of this. The fact that they were given a categorical assurance that they would be consulted about any proposal that the Astronomer Royal post would be divorced from the directorship of the RGO, but nevertheless were not consulted about it at all, is only an unusually dramatic illustration of why the management is losing the confidence of its staff. Nor does the explanation which has now been given make things any better.

But it is the affair of the Northern Hemisphere telescope which has caused the greatest anxiety. As you point out, there have been powerful pressures in favour of creating a third administrative centre in the UK for the Northern Hemisphere telescope. This should be a scientific and administrative responsibility of the SRC as such, one of whose responsibilities it is to provide facilities for common use by a variety of university scientists. The logical site for the centre is at the RGO—or, alternatively, at the Royal Observatory Edinburgh—but it appears as if there has been tremendous opposition to this. To establish one university rather than another as a third centre for the handling of common facilities would surely be contrary to the purpose of the SRC, as well as being unnecessarily costly; and there is no point in having a third centre all by itself.

It is also the function of the SRC to do its own research at its own establishments, and a considerable number of first-rate scientists are employed on its staff for this very purpose. Collaboration with universities in the use of scarce facilities and equipment held in common by the SRC is fully accepted by the staff and by the institution. It is one of the purposes of SRC to bring about this collaboration, and such differences as there may be from time to time between the SRC's own scientists and those from universities should be concerned with nothing more than matters of balance. The affair of the Astronomer Royal has raised the question, however, of whether it is a question of balance. The policy of the Science Research Council is in the hands of the majority of university representatives on the council, and in a period in which there is keen competition for the relatively limited amount of money available, the SRC's own scientists are looking for reassurance about the long-term standing of their own research work.

Not only are they not getting it, but they can see no means by which, within the SRC as it stands, they can right the balance if it tips too much in the universities' direction.

Yours faithfully,

JOHN LYONS
Deputy General Secretary.

Orbital Planes of Planets

SIR,—Recently (April 26) we attended a lecture at the University of the South, Sewanee, Tennessee, by Dr Peter Van de Kamp of Sproul Observatory, Swathmore, Pennsylvania. He spoke on "The Search for Extra-Solar Planets", his work for 35 years, which indicates that Barnard's star has two planetary companions bearing a similarity to Jupiter and Saturn.

This lecture restimulated an idea held by one of us (Wells) for several years. We know the ecliptic plane is practically at right angles to the plane of the galaxy, but we don't know if this is only by chance or of deep significance. After the lecture Dr Van de Kamp was asked if enough was known about the orbits of stars with companions to determine orbital planet orientation. He said he had not considered it but some work might well be devoted to the question. He commented on the planes of binaries as being apparently random.

During the 70 mile drive home, we discussed this further. It was decided that, since Dr Van de Kamp had not investigated this relationship, it may not ever have been properly considered.

It seems that one of the most fundamental bits of information that could come of extra-solar planet searches would be a determination of the distribution of orbital planes. If other solar systems besides ours should be found with the orbital planes also at right angles it would be suggestive, with probable implications for galactic evolution, as indeed would any significant deviation from random orientation of orbital planes.

Should a preferred orientation be established, it could have a great bearing on theories of galactic dynamics. It would seem that our solar system may have been formed approximately 90° from the present galactic location initially, since difficulties are foreseen in trying to reconcile the ecliptic angle with fluid mechanics or condensation theories.

If we should be able to determine the plane of other ecliptics around other stars, it would greatly simplify the search for extra-solar planets by determining the directions from the stars to expect planets; a great advantage in radio astronomy or other scanning methods. For instance, Project Ozma was apparently limited in scan directions.

It was felt that this letter might bring comments from others on this question and help keep it before the attention of astronomers who might be able further to evaluate and pursue the phenomena.

Yours faithfully,

ERNEST H. WELLS

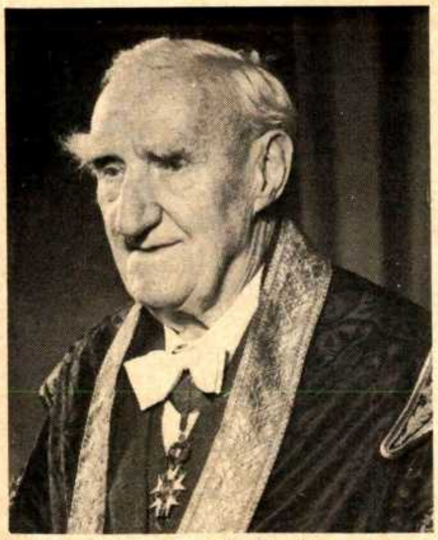
Obituary

Lord Boyd Orr



LORD BOYD ORR of Brechin Mearns, Nobel Peace Laureate, Chancellor of the University of Glasgow, first director-general of the United Nations Food and Agricultural Organization, first director of the Rowett Research Institute and founder of the World Food Council, died on June 25 at the age of ninety.

John Boyd Orr was a graduate in arts, science and medicine of the University of Glasgow, where he also obtained his MD and DSc. His first external appointment was to a new research post in Aberdeen linked to the College of Agriculture and the university. This subsequently grew into the Rowett Research Institute. However, before he could get established the First World War began. Until 1917, he served with the RAMC, winning the DSO and MC with bar. Later he undertook an investigation of the physical requirements of servicemen for the navy.

Some of his first experience in nutritional investigation was gained in collaboration with the late Professor E. P. Cathcart at Glasgow. Here he worked chiefly on water and protein metabolism and on energy expenditure during work. There he was influenced by research on the diet of the working classes. On moving to Aberdeen, he took the advice of Cathcart and studied the mineral metabolism and needs of farm livestock, developing both topics with characteristic energy and insight. Some of his most impressive work was on mineral deficiencies and soil exhaustion in relation to pasture production both at home and abroad. This led him to establish a clinical unit to investigate the effects of husbandry techniques on the human populations of Masai and Kikuyu. It also established his interest in nutrition and disease and their interrelations.

He was responsible for great improvements in the production of meat, wool and milk, and helped to bring prosperity to the livestock industry. He gave the farmer more precise knowledge in the selection of food mixtures as a substitute for growing pastures, particularly in the wintering of his stock. He also gave some definition to the biochemical and immunological changes which precede and accompany the general symptoms of disordered metabolism caused by nutritional deficiency or imbalance. After starting work at the institute in a cellar of Marischal College, Orr received the financial backing of such men as Dr John Quiller Rowett (after whom the institute was named) and was able to establish at the institute the Imperial Bureau of Animal Nutrition.

Orr's professional concern was with animals of agricultural importance, but he found that whereas he had no difficulty in persuading farmers of the value to their stock and pockets of the application of sound nutritional principles, he could not convince anyone that the same was true of children. At that period the nutrition of man himself was an art rather than science, empiricism rather than experimentation, general impressions rather than controlled observation. But now, the newer knowledge of nutrition was growing, requirements could approximately be defined, and dietary surveys could expose the gap between requirement and that consumed. A large scale demonstration of the nutritious value of milk for school children partly done to promote the increased consumption of milk for the benefit of the dairy industry, but primarily done to promote the health of the children whom he suspected of being undernourished, led to further work on human nutrition. With government financial help he undertook the survey which became a classic: *Food, Health and Income,* and was first published in 1936 and had world-wide repercussions.

Then there followed the more extensive dietary and clinical surveys of representative groups of families with children of varying income levels in many parts of Britain, which further demonstrated the relation of food, health and income, and the consciousness of this on a world scale grew into a natural and later international food policy based on human needs. This was supported by Carnegie UK Trust funds. Such was the value of this accumulated knowledge of human needs and intakes that Orr was able to so advise the Government on the scientific food policy during World War II that we were able to emerge in a better nutritional state than when we entered, for rationing was based on needs and not on purchasing power. Further, these observations and knowledge displayed by Orr so impressed the United Nations that Sir John Orr—as he then was, having been knighted in 1935—was appointed at the Quebec Conference the first director-general of the Food and Agricultural Organization, coinciding with his retirement from the Rowett Research Institute in the autumn of 1945, and this post he held until 1948. It was on the platform or at the conference table that his biggest personal impacts were made.

He was lean with craggy eyebrows, long jawed, and although he had no tricks of oratory, the single-mindedness of his argument—one thing at a time—and his prophetic sincerity generally won the day. Some thought him naïve, but it was an expressed simplicity with a purpose. His hunches were very sound: he was sometimes impatient of the slowness of the research worker to corroborate what he felt in his bones to be valid and vital.

Orr inherited much of his strength of character from his mother, who was a Boyd. In 1915 he married Miss Elizabeth Pearson Callum, of West Kilbride. They were seldom separated and travelled the world together. She was a wonderful partner and ambassadress. He is survived by his wife and two married daughters. Their only son was killed on a Coastal Command mission during the war.

Announcements

International Meetings

September 15–17, **British Society for Cell Biology Meeting,** Bristol (Dr J. M. N. Boss, Department of Physiology, Veterinary School, Park Row, Bristol BS1 5LS).

September 20–21, **Small Craft,** Southampton (Royal Institution of Naval Architects, 10 Upper Belgrave Street, London SW1X 8BQ).

September 21–23, **Infrared Techniques,** Reading (Conference Department, Institution of Electronic and Radio Engineers, 8–9 Bedford Square, London WC1B 3RG).

September 28–29, **Biochemistry, Genetics and Therapy of Schizophrenia,** London (Schizophrenia Association of Great Britain, Llanfair Hall, Caernarvon).

September 28–29, **Ultrasonics 71,** London (Mr A. H. Crawford, Ultrasonics 71, 32 High Street, Guildford, Surrey).

October 11–12, **Natural Slopes Stability and Conservation,** Naples and Cosenza (Dr G. Guzzetta, Istituto di Geologia, Naples, Italy).

October 18–22, **Eurocon 71,** Lausanne (Eurocon 71 Office, 24 Chemin de Bellerive, CH-1007 Lausanne, Switzerland).

November 10, **Medical Thermography,** London (Warren Cook & Partners, Woodfield House, Goudhurst, Kent).

November 11–12, **Coatings,** Great Malvern (M. G. Bader, Department of Metallurgy and Materials Technology, University of Surrey, Guildford, Surrey).

November 11–12, **Endocrine and Non-endocrine Hormone Producing Tumours,** Houston (Mrs Jane Brandenberger, Information Coordinator, University of Texas M.D. Anderson Hospital and Tumor Institute, Texas Medical Center, Houston, Texas 77025, USA).

NATURE Volume 232 AUGUST 27 1971

From Intelsat to Aerosat

REPRESENTATIVES of fifty-five countries turned up at the State Department in Washington last Friday to sign the inter-governmental agreement creating the new international communications satellite organization, Intelsat. The name of Intelsat, of course, has been wafting about for about seven years but it was referred to the temporary consortium, set up in 1964, to make a commercial global network out of communications satellites which at that time were merely in the experimental stages. The new Intelsat, unlike the old, will have juridical personality and an international executive. Yet the seven years of Intelsat's interim life were not happy ones. The practical success in putting geostationary satellites into service over the Atlantic, Pacific and Indian Oceans has been soured by the bitterness over the way that the organization representing the United Sates, Comsat, the communications satellite corporation, dominated the consortium. The European industrial nations who were among the participants of the original agreement never won anything like the share of the contracts that they had once hoped for. Of the dozens of costly Earth stations built around the world to work with the system, for which non-American suppliers were more readily available than for the satellites themselves, the great majority were built by American companies. So great was the resentment over this and over the American antagonism toward regional communications satellites outside the Intelsat system, that France, one of the original signers of the 1964 agreements, did not sign last week. Neither did Belgium, Mexico and West Germany, although all may at a later time.

In the new Intelsat the American influence is considerably reduced. Under the old arrangements, the United States held a majority of the voting shares and could not slip below 50.4 per cent. Britain was a poor second with less than 10 per cent (the percentages varied as new members—eventually 80—joined Intelsat). But the American dominance went beyond that. Comsat was the autonomous manager of the system and as such was not very forthcoming about the reasons and financial details about the contracts which it prepared on Intelsat's behalf. Both the American State Department and Comsat were dismayed to find, as the negotiations for a permanent agreement began, that Britain joined with the Europeans in fighting for a more internationally balanced organization.

That has been achieved but it is pyrrhic victory. In the first place, three expensive, tedious and acrimonious international conferences were needed to reach the two agreements (one for governments, one for telecommunications entities like Comsat and the British Post Office) which were opened for signature last week. In the second place, the organization that has resulted from all the wrangles and compromises is over-structured—over-defined to the point where it will be weak and inflexible in considering the new services which communications satellites may offer in the late 1970s and early 1980s.

The new Intelsat is to have four parts. The most powerful will be the Board of Governors on which the biggest investors will be represented, with their votes weighted according to the size of their investment. One restriction on Comsat has been built in here, for no country may have more than 40 per cent of the vote. The other significant thing about the board is that its representatives will be telecommunications men, which will severely limit Intelsat's capacity to develop satellites for air navigation, weather mapping or any kind of communications except public telecommunications services. Another part will be the Assembly, where each member country will have one vote. The Assembly will have no power to make decisions or to dictate to the Board of Governors. All it can do is to make recommendations about general policy—a victory for the United States and a defeat for the developing countries, which wanted a strong Assembly as they will have little or no voice in the Board of Governors. There will also be an international directorate to handle the day-to-day affairs of the organization. Nothing like this existed under the temporary arrangements. The directorate will be headed for the six years after the agreement comes into force by a secretary general, whose function will be to monitor Comsat in its performance as manager. Then after six years, he will be superseded by a director general.

The fourth part of Intelsat is the management, which handles the practical operations of the system. The contentious question—will Comsat continue or not?—has effectively been shelved for six years. Comsat will continue for that period but under a contract limiting its tenure and then by 1978 must apply for the job together with any other organization which may present itself. Comsat is by no means certain of holding on. A European aerospace consortium might by then be qualified to manage a satellite system. The Hughes Aircraft Company, the world's major satellite builder, would qualify now; so would the National Aeronautics and Space Administration. Thus the fights over management seem doomed to be prolonged and renewed during the very years when Intelsat, as it tries to pull itself together as a fully-fledged autonomous organization, should be coming to grips with more important questions, such as persuading the Russians to join, at least to agree to terms of practical cooperation between Intelsat and its own proposed Intersputnik international satellite system.

Just how limited Intelsat is in scope was shown by the agreement reached in Madrid earlier this month on an experimental aeronautical satellite system. The project was agreed on and will be carried out by the American Federal Aviation Administration and the European Space Research Organization and other participants. The plans are firm and clear: a pre-operational network of four geostationary satellites by 1974 with the aim of a fully operational network by 1980. It is hoped that a formal memorandum of understanding will be signed by November. Not only will the experiment have nothing to do with Intelsat, it will not even use Intelsat as a model. (Great hopes had been fixed upon Intelsat as a model for international commercial technological cooperation.) In fact, it will be at some pains to avoid Intelsat's mistakes.

A council called Aerosat is to be formed, composed of an equal number of representatives of the United States and Europe, and one representative from the government of each of the other interested countries (Australia, Japan and the Philippines). At the same time, there will be an executive office with its staff equally balanced internationally. The council will attempt to prepare a final document proposing the specifications of the desired satellite. There is no question but that the satellites will use the UHF band, something that both the FAA and ESRO have agreed on, to the chagrin of commercial international airlines who would prefer a less costly VHF system. The money—about $150 million—will be provided by the participating governments.

The advantages will be great. Various governments will not have to bear the expense of proceeding with aeronautical satellite experiments separately and perhaps incompatibly. Eventually separation between aircraft flying routes such as the heavily congested North Atlantic will be substantially reduced. The present methods, in which aircraft cannot be pinpointed more accurately than to within ten miles, requires a horizontal separation of 120 nautical miles and a vertical separation of 2,000 feet. The specifications laid down for the experimental project would permit aircraft to be placed within one half mile of their actual position and to fly as close as 30 nautical miles apart, separated vertically by 1,000 feet.

What Market for Computers?

THESE have been bad times for computer manufacturers in Britain, those owned by British interests and those which operate in Britain as subsidiaries of parent companies in the United States. For several weeks now, there has been a steady stream of news of how computer manufacturers have been shedding their labour forces. A week ago, the Department of Trade and Industry provided statistics to show how sales of computers have declined both in Britain and in the British export market. The decline of business has been dramatic. The total deliveries of computers from British manufacturers declined between the last quarter of 1970 and the first quarter of 1971 from £79 million to £64 million, a decrease of 18 per cent. This is more than a seasonal effect. Deliveries of computers have risen steadily, quarter by quarter, since 1966 but appear to have reached a peak of £85 million in the third quarter of 1970. The decline in the export business has been particularly sharp. Home deliveries fell by ten per cent between the lasts quarter in 1970 and the first quarter in 1971, but export deliveries fell by no less than 33 per cent. In practice, roughly half the lost market consists of machinery which is assembled in Britain from components imported from elsewhere. There was actually a small increase of six per cent in the value of British-made computers delivered to the British market. And if the manufacturers are cast down by their statistics for equipment delivered, they must be even more depressed by the order books, which have been falling since the beginning of 1970 and which, by the beginning of this year, had become so meagre that there is bound to be a further decline in sales as this year wears on.

What has gone wrong? Why has the great fashion for computers been undermined so quickly? In the past few weeks, it has been frequently suggested that the potential purchasers of computing machinery have been discouraged by their own experience of the failure of computers to function properly, or at least as well as the prospectuses for them claim. Is it the case that as with other technical innovations of the past few years—nuclear power, for example—the usefulness of computing machinery has been diminished by optimistic and unattainable promises of what these innovations might accomplish? By all accounts, there is a good deal in this view. After all, the British experience in the past few months is only a more dramatic representation of what is happening elsewhere, particularly in the United States. Small and smallish companies of all kinds are everywhere to be heard complaining that the machinery which they have installed in the past few years has failed to do the job required of it. Core storage turns out to be too small for what it has to remember. Processors turn out to be much slower in practice than they are in theory. The costs of producing software, in any case, substantially incalculable, turn out to be formidably high. And all too often the purchasers of computing machinery discover that their new computer does not help them to reduce the costs of operations or even to undertake fast clerking operations without anxiety.

Salesmen are not solely to blame, although many companies have done themselves a lot of harm by over-selling. There are, however, serious problems of a technical character. Computer people are the first to say how important is the systems approach to practical problems. For an innocent company about to buy a computer for itself, what this implies is that the potential customer has—or should have—a clear idea of what he would like the machine to do but no great concern about the precise manner in which it will function. To be sure, there is much in the view that one of the uncovenanted benefits of acquiring a computer is that it compels those who would use it to understand the business in which they are engaged. But there are limits to what the systems analysts are entitled to claim in this respect. After all, the installation of a new computer system is not an end in itself, or should not be, and it is beyond dispute that the upheaval entailed is in itself a real disincentive. The moral is that manufacturers should as a matter of course sell (or offer to sell) more than a machine—the software should go with it. But it is by now quite clear that the software as sold commercially is often outrageously expensive. If manufacturers want to keep their order books full, they will take steps to see that the machines they sell do actually perform as advertised. Such a goal could bring quite a different structure for the computer industry. As things are, manufacturers have assumed that their profitability is best ensured by apeing the motor car industry and setting up production lines for turning out replicas of more or less identical machines. Although there is undoubted scope for arrangements under which computer complexes can be assembled from smaller parts so as to provide each potential customer with a custom-assembled complex, this is only a beginning. Might it not be more profitable for the manufacturers to find some way of standardizing on software even if this meant that the machinery had to be more sensitively adapted to the customer's needs.

Compromise Without Solution

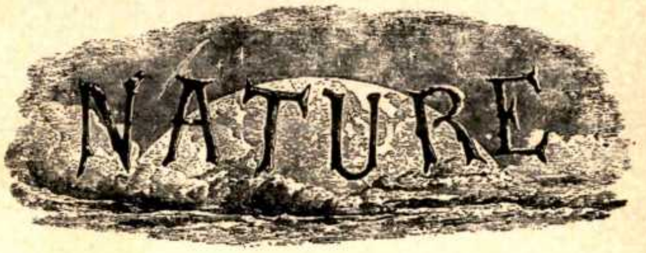
EVERYBODY knows by now that an arbitration tribunal inquiring into a pay dispute can usually be relied on to split the difference between the two opposing sides. This, predictably enough, is what the public inquiry into the salaries of scientists in the British civil service has done (see page 594). Those who had been offered nothing are now to get an extra five per cent. Those who had been offered something, for practical purposes about ten per cent, will have to be satisfied with that. With masterly empiricism, the tribunal says that the award "seeks to apply the principle of fair comparison and pay research taking into account the special features of a scientific career in the civil service and the fact that the pay of the scientific grades has been determined hitherto by horizontal relativity" without saying why it considers that the arguments put forward by the Civil Service Department in the past few months were invalid, as the Institution of Professional Civil Servants has been claiming. Indeed, the tribunal has the gall to say that "the award should in no way be taken to prejudice future decisions about the unified grading of the scientific and other classes". In other words, the tribunal has casually discarded one of the principles used in previous inquiries like this but has neglected to suggest a replacement. Nobody can be blamed for reacting vigorously to this development. The Civil Service Department will have only itself to blame if the Institution of Professional Civil Servants now becomes a constant thorn in its flesh. Unhappily, even the institution is a long way from recognizing that the time has come to take a much more radical view of the framework within which professional scientists should be employed by the British government.

The most obvious difficulty is that the scientific civil service has become a genteel blind alley for a great many of those who work in it. This is the point that the Fulton commission made. In practice, it has been exceedingly difficult for civil servants who begin as scientists to become, in the course of time, administrators of a more conventional kind. A part of the reason, no doubt, is that many working scientists in the civil service prefer to stick to science—not all of them complain. But it is beyond dispute that for a great many people who would normally expect in other walks of life, in industry for example, to move sideways from research into administration, the present rules are cramping. It is true that the Civil Service Department has been looking for recipes for transforming the civil service along lines that might have been suggested by the Fulton commission and that, ironically, discussions on these have been in part held up by the pay dispute. In the meantime, however, it is plain that the very large proportions of people who have accumulated in the higher grades of the scientific civil service are a measure of the extent to which there are few ways out at the top.

What is to be done? The first thing to recognize is that to the extent that many professional scientists in the civil service value their professional connexions as much as their status in the hierarchy, there is a strong case for hoping that it should be made comparatively easy for them to leave the civil service for other kinds of work. In other words, there should be much easier machinery by means of which scientists in the civil service could contract out of the arrangements which are conventional. In particular, it should be much easier for them to take their pensions with them if they are so inclined. The simplest way of arranging this would be to arrange that the Civil Service Department would convert into cash or its equivalent the accumulated pension rights of somebody wishing to leave. To be sure, this might often mean that the civil service would lose many men of promise and attainment, but then the question arises what in any case is the civil service for? Is it really meant to be an organization primarily concerned with its own perpetuation? Or should it be more eager than it is to help spread its skill about the country? These and related questions are the ones which the Institution of Professional Civil Servants should now be asking. It would be a great misfortune if they become entirely lost in detailed quibbles about the most equitable way of comparing dissimilar kinds of careers.

---

100 Years Ago



IN his last weekly return, the Registrar-General refers to the westward advance of Asiatic cholera as investing with more than ordinary interest Dr. Frankland's usual monthly report upon the quality of the metropolitan water supply. The water supplied by the New River and Kent Companies is again reported freest from organic impurity, that of the East London and Chelsea Companies the most impure. With reference to the advantage which would be derived from a general application of Dr. Clark's softening process to the London water supply, the Registrar-General adduces the following valuable facts, which have been communicated by Mr. Robert Rawlinson, C.B., C.E.:—"The average daily water supply to the metropolis was 111,292,104 gallons in June, and 112,107,697 gallons in July. Now in each million gallons of these waters there is about one ton of bi-carbonate of lime, or 111¼ tons in June and 112 in July. About two-thirds of this weight of lime or chalk would be removed by Dr. Clark's softening process—that is, in June 74 tons, and in July about 75 tons. In each year about 25,000 tons of useless lime would be removed from the metropolitan waters by the simple and easy process now in use at Canterbury." The Registrar adds: "This riddance of the foreign matter, which deprives water of some of its cleansing properties, is in itself an advantage; but, besides this, the fine precipitate of chalk carries down with it suspended impurities and probably frees it from choleraic and other contagions. It is a most effective filtration." It is a comfort to know that the working classes are beginning to feel their strength. When that is put forward it is certain to be in the direction of sanitary and educational measures. The Registrar-General appends to his report a concise sketch of the steps proper to be taken in view of the threatened epidemic.

OLD WORLD

SCIENTISTS' PAY

Splitting the Difference

The announcement last week of the award of the Civil Service Arbitration Tribunal to scientists employed in government laboratories brings to an end the first round of the dispute between the Institution of Professional Civil Servants and the Civil Service Department that has gone on since early in June. The IPCS, however, is far from satisfied with the result and is already preparing a campaign to change the whole process of pay determination for government scientists.

The IPCS, after asking for an overall increase of 14.1 per cent for members of the scientific classes, was offered 2.5 per cent by the Civil Service Department—with no increase for the higher grades. The arbitration tribunal awarded 5 per cent to the higher classes not offered any increase originally but was more open-handed with the Scientific Assistant classes. Otherwise the tribunal mostly confirmed the original Civil Service Department offer, details of which were given in *Nature*, **232**, 512; 1971. The Senior Scientific Assistant class was awarded a 5 per cent increase compared with the 10 to 15 per cent asked for and the 2.5 to 3 per cent offered. The Scientific Assistant class received the largest increase with the minimum of the scale being increased from £490 to £550 and the maximum from £1,253 to £1,395—very near to that demanded by the IPCS. The total award amounts to a 7.5 per cent overall increase and will cost the government nearly £2.5 million annually.

The Civil Service Department has cause to be pleased with the award as Mr Mustill, QC, the tribunal chairman, and his fellow members, state that "the award seeks to apply the principle of fair comparison and pay research that also takes into account the special features of a scientific career in the Civil Service".

The IPCS has argued vehemently against this principle (see *Nature*, **232**, 512; 1971) and believes that the pay of the scientist should be based solely on internal relativities. Mr William McCall, the general secretary of the IPCS, considers the award to be thoroughly unsatisfactory and he said last week "(the award) has attempted to produce a compromise between internal relativities and pay research. What it has achieved in fact is a complete mess. The award resolves none of the basic issues involved in the arguments to the tribunal. Indeed, the award marks the beginning of a dispute, not the end of it. It is plain from the statements of cases submitted to the arbitration tribunal that the salaries indicated by internal relativities cannot be reconciled with pay research information".

The IPCS will face an uphill task in its campaign to determine scientists' salaries in the future by some means other than pay research. Most other salaries within the Civil Service are directly or indirectly determined by pay research, and it will need a very strong case to place the scientific classes outside this scheme. The IPCS is confident, however, that this can be done, and at the moment is pressing for a joint review body of the Civil Service and IPCS to be set up to decide how scientific salaries are to be determined in future. As yet there is no reaction from the government to this suggestion, but it does seem likely that round two is about to start.

ELECTRONICS

Microcircuit Trouble

The British microcircuit industry is in decline as the world demand for integrated circuits continues to dwindle and overproduction increases. Companies are now faced with the extraordinary situation in which integrated circuits are being sold in the United States for less than the estimated cost of the raw materials and at only slightly higher prices in Britain. Manufacturers such as GEC-Marconi seem to be resigned to cutting production and closing factories.

What has caused such a state of affairs in which an American company, Texas Instruments, can now sell for £0.05 an integrated circuit that would have cost £3.00 in 1967? The first thing to say is that manufacturers of integrated circuits throughout the world are experiencing similar difficulties. Overproduction in the past few years has been the inevitable result of a rapid increase in production efficiency—better crystal growing techniques and a smaller rejection rate for completed circuits, for example—coupled with a reduction in the rate of increase of world demand. Companies that expanded their manufacturing facilities a few years ago, and then gritted their teeth while prices tumbled, are now obliged to prune manufacturing capacity thus losing skilled workers and running the risk of falling behind technologically. Those companies that can resist this inexorable process will presumably reap the benefits eventually.

During the past few months GEC-Marconi has announced the impending closure of its integrated circuit factories at Witham and Glenrothes after sustaining a loss of £1 million on these activities in 1970. Mullard lost £1.4 million on its microcircuit sales last year and Texas Instruments has made several hundred people redundant at its factory in Bedford. The state of the British market during the past few years is shown in Table 1; price reductions and the small growth in demand have both contributed to the relatively meagre increase during 1970.

Table I. Annual Sales of Microcircuits in Britain

1966	£2.6 million
1967	£4.8 million
1968	£7.8 million
1969	£15.4 million
1970	£17.0 million

About half of the British integrated circuit requirements in 1970 were imported and 43 per cent of these were supplied duty free from the Free Trade Area and from Singapore (where they are chiefly manufactured by American companies). Most of the other imports were of integrated circuits manufactured in the United States and packaged in cheap labour areas such as Taiwan, Korea and Portugal; these are still relatively inexpensive in Britain in spite of the 20 per cent tariff.

The total British market is much smaller than the domestic market in the United States (about £180 million in 1970) and fluctuations in the American market obviously have serious repercussions in Britain as American manufacturers try to keep production lines going by continuing to sell at a loss. Some Members of Parliament have indeed suggested that integrated circuits are being dumped in Britain and have called for additional tariffs or import quotas, but there is no doubt that dumping, in the strict sense of the word, cannot be taking place when the same integrated circuits are being sold more cheaply in the United States.

ENGINEERING

More Grades Invented

The Privy Council has now approved the request by the Council of Engineering Institution to set up an Engineers' Registration Board (ERB) providing a composite register of Chartered Engineers, Technician Engineers and Engineering Technicians. The ERB will comprise institutions and societies that are involved in education and training of their members in one of the above categories.

The aim of the ERB, according to the Council of Engineering Institutions, is to rationalize the qualifications of engineers and to give the engineer an identity. The three classes of membership suggested will carry the letters C.Eng., T.Eng.(CEI), and Tech.(CEI), and the qualifications for membership are a degree or equivalent in engineering for the C.Eng., a Higher National Certificate or City and Guilds Full Technological Certificate for a T.Eng. (CEI) and an Ordinary National Certificate or a City and Guilds Part II Final Technicians Certificate for a Tech.(CEI). Membership also requires appropriate training and experience in all categories.

The C.Eng. qualification is not new and was first instituted when the Council of Engineering Institutions was formed in 1965. The two new classes now instituted will, it is hoped, supersede 50 or 60 titles that have been in use for many years all with different qualification standards. Whereas the Council of Engineering Institutions does not expect all engineers to apply for membership immediately, a spokesman said this week that the eventual goal is to have the presently instituted qualifications accepted as the standard by all British engineers.

Engineers can be nominated to the register by one of the fifteen constituent members of the ERB. There will be no fee directly paid to the board by the engineer—his membership of the parent institution will be sufficient to qualify for membership. The member institutions are enthusiastic about the setting up of the Engineers' Registration Board, but as yet they have not tended to approach their corporate members to ask their views. There seems to be no reason why members should not share this view.

SCIENCE MUSEUMS

Summer Boom in London

IN the summer months, attendance at the London museums reaches its annual peak and the Science Museum and the Natural History Museum—the British Museum (Natural History) as it calls itself—is sharing in the popularity. The Science Museum has had more than 2,000,000 visitors a year since 1968 and the Natural History Museum has some 1,500,000 visitors a year—a figure that is increasing at 10 per cent a year.

But who comes to the museums, and what do they offer? There are no detailed statistics, although a survey that would establish this has been suggested at the Central Office of Information—but both museums know they have to cater for large numbers of children. The Natural History Museum has it down to a considerable art, with a special Children's Centre open on Saturdays during term and six days a week during school holidays. This helps children to find their way constructively around the museum by providing them with "Nature Trails" and encouraging those showing a genuine interest to join the Natural History Club which meets on Saturdays, when a certain amount of field work is done. There are close links with schools and teachers, and school parties are frequent. From a small random survey last winter, the Natural History Museum has some idea of the age distribution of its visitors—65 per cent of them are under thirty, over half of those are under twenty, and the survey excluded school parties, which provided just under 120,000 visitors in 1970.

The Science Museum has no such figures, but it thinks that one third of its visitors are children and that an appreciable proportion of them come time and again. Arrangements for seriously interested children are meagre, although the museum does run an increasingly comprehensive and varied set of lectures and tours. There is no equivalent of the "Nature Trails"—an experiment with a similar scheme is said to have turned out to be administratively and technically unmanageable. There is, however, some contact with schools and the special Children's Gallery, transferred to a larger location in the basement some two years ago, is as popular as ever. The transfer has allowed for several new exhibits to be included together with the old favourites.

Since 1963, the work of modernizing the exhibitions has progressed gallery by gallery, for the museum is aware that even if new exhibits are continually installed, the design of a gallery dates over the years. A spokesman said that plans are also afoot to redesign the mathematics gallery to include information on computing—a feature that has been sadly neglected to date—with the possibility of a working computer terminal. A section on production engineering is also planned, and both schemes should increase the topicality of the museum.

Although the museum itself makes no complaint, the sum available for new acquisitions is only £8,000 a year, a frighteningly small amount of money if the museum is expected to keep any sort of pace with scientific and technological developments. In spite of the attraction for children in the many working models, the museum does not consider itself primarily for children. They feel that their research facilities are an important part of their work, and that the main aim of the public galleries is to arouse people's curiosity, and possibly stimulate them to a deeper interest.

The Natural History Museum fills rather a different role from the Science Museum. Despite its large public halls, its purposes lie rather in the fields of active research, which the new wing, and the new building at Tring, at present under construction, will help to further. Established in 1881 on a taxonomical basis, the museum is now questioning the validity of this as current research shows more and more that animals and organisms should be considered in their environments, and a spokesman said there may be changes in the future to base the layouts on ecological principles. Before this can be fully accomplished more exhibition space will be needed.

Nevertheless the main purpose of the museum is always likely to be one of research, partly because of the impossibility of displaying more than a small percentage of the natural world—for example the museum owns some 250,000 mineral specimens alone, of which only 4 per cent are on display—and partly because there is much still to be made known about the natural world. After all, although there are some 750,000 known species of insects, it is estimated that there are between two and four times as many yet to be identified.

CONSERVATION

Just for the Birds

THE Royal Society for the Protection of Birds has recently established a 335 acre reserve in the Dale of Cottascarth on the mainland of Orkney. The society, which manages more than forty other bird sanctuaries throughout the British Isles, chose this northern site because there are a number of typical habitats of the birds that breed in Orkney within its boundaries. These reserves are an attempt to maintain the natural integrity of wildlife communities and those that have been in existence for some time have been very successful in this purpose. Access is restricted to members of the society, although this year saw the well established reserves open their doors a fraction to let in small numbers of the interested public. The doors are unlikely to open much wider, and understandably so for the birds' sake.

With the ever-increasing popularity of Orkney with holiday-makers, the establishment of the Cottascarth reserve is wise and timely. The Dale is, in fact, scheduled by the Nature Conservancy as a site of special botanic interest.

NEW WORLD

Drug Office Wins Friends, Disarms Enemies

by our Washington Correspondent

ONLY two short months have now gone by since President Nixon announced to Congress and the nation his war against drug abuse, and already two Congressional committees have concluded hearings on legislation designed to put into effect his package deal setting up a Special Action Office for Drug Abuse Control, with additional funding of $155 million for the control of drugs and the rehabilitation of addicts. Both committees—the House Subcommittee on Public Health and Environment and the Senate Subcommittee on Intergovernmental Relations—are expected to report to Congress soon after the recess, and it seems from the evidence submitted to the committees that the President's proposals should emerge substantially unchanged. The programme has met with approval even from the agencies whose work will be subordinated to the new special action office.

Chief among the tasks of the proposed action office is to coordinate the federal programmes for drug control and rehabilitation, at present spread over nine agencies of the Federal Government. To accomplish this task, the Special Action Office will have at its disposal the effective and overtly simple expedient of complete budgetary control over all federal drug abuse programmes. But creation of the special action office will also underline a marked shift in the government's attitude to drug control, for in the past it has relied heavily on the courts to deter potential addicts from taking drugs, often at the expense of seeming to neglect the other side of the coin—the rehabilitation of existing addicts. Only the full realization of the extent of heroin addiction among troops in Vietnam which came to light about a year ago, and the potential impact of thousands of addicts returning to the United States from Asia has led to the tardy adoption of a crash programme aimed at rehabilitation.

While the new emphasis away from severe court action brought against drug users and towards education and rehabilitation has been widely applauded, there are still many doubts surrounding the way in which the new special action office will function. One such doubt is whether the director of the office will be able to exercise complete control over the budgets of the agencies in his jurisdiction without at the same time running up against resentment within the agencies themselves at their loss of effective power. As James W. Symington, a member of the Subcommittee on Public Health and Environment, said to Dr Jerome H. Jaffe, Nixon's nominee to head the action office, "in every one of those agencies there is a fellow that has the responsibility right now to see how much they can afford, where it ought to go, and how he exercises that responsibility depends on the multiplicity of contacts that agency has in the states and localities. But you are going to understand all of that for every agency, put it together and then explain to them how to handle it. Congratulations and best wishes".

In many respects, the appointment of Dr Jaffe to the post of director has circumvented a few of those fears, for Jaffe is respected by all the agencies with which he will be dealing. In particular, he has served for several years on the board of the National Institute of Mental Health, whose Division of Narcotic Addiction and Drug Abuse will consume some 70 per cent of the Special Action Office's funds. During that time, Jaffe has built up a strong working relationship with the NIMH staff which will stand him in good stead for regulating their budgets. One official of the NIMH said last week that he regards the special action office as a powerful ally to fight for funds and that there should be no problem in the transfer of power from the NIMH to its drug overlord.

How Jaffe visualizes the work of the special action office became clear during his second appearance before the subcommittee earlier this month. He explained that the office would not seek to meddle closely in the work of the various agencies, and that it would take over the running of a particular programme only as a last resort. The office is therefore intended to be an overlord, working chiefly by informal contact and discussion with the members of the agencies under its control, acting as their mouthpiece in Congressional hearings, and using its powers to seek appropriations for drug abuse control and to distribute federal monies.

Applications for funding for new projects will be channelled through the office, and Jaffe will be concerned especially to see that there is no duplication of effort among federal agencies. The arrangement also has the potential advantage that it may help to speed up the adoption and funding for new projects, for they will no longer be buried within the bureaucratic layers of each individual federal agency.

If the house subcommittee on Public Health and Environment does alter the Administration's legislation, it seems likely that the powers of the proposed special action office will be widened rather than cut down, for there has been some disquiet that the Department of Defense is not included among the Federal agencies controlled by the office. Jaffe, however, has said that there would be no particular advantage in his having budgetary control over the Defense Department's drug abuse programmes, because any necessary coordination can be achieved by informal discussion.

One aspect of the drug problem in which the attitude of the Department of Defense is particularly important, however, is to establish the terms under which a member of the armed services is given a dishonourable discharge. In the past, services personnel have been given a dishonourable discharge for drug addiction, and this has prevented them from receiving treatment in the clinics run by the Veterans Administration.

There is also the problem of administering tests on servicemen for the presence of opiates in the urine, prior to discharge. It has recently been found from such tests that 5.4 per cent of American servicemen in Vietnam had used heroin in the two days before the test was given. The test, which was given on a random basis, almost certainly provided an underestimate of the number of servicemen taking hard drugs, and Jaffe himself believes that the true figure is probably nearer 10 per cent. It therefore seems likely that the subcommittee will add the Defense Department to the legislation in the hope that the Special Action Office will be able to coordinate not only the testing of American servicemen for the presence of hard drugs, but also the treatment of addicts in the armed services.

If the Special Action Office is set up, it will have an initial lifespan of three years, when its operations will be reviewed by the President. There is little in either the proposed legislation or in the steadily increasing figures for drug addiction—it is estimated that there are now about 250,000 heroin addicts in the United States, and probably 150,000 in New York alone—to suggest that the problem will be any less acute in 1974. But at least a change of direction in favour of rehabilitation is a comforting sign of the Administration's intentions.

Ailing Health Services

by our Washington Correspondent

A BATTLE is developing between Congress and the Administration over plans to transfer a narcotics rehabilitation and clinical research centre at Fort Worth in Texas from the Public Health Service to the Bureau of Prisons. The Administration stands accused of effectively shutting down much-needed facilities for the rehabilitation of addicts at a time when a drive against drug addiction has been labelled a national priority.

Congressional opponents of the plan led by Paul G. Rogers, chairman of the House Subcommittee on Public Health and Environment, seem assured at least of staying the execution for another year. A congressional victory may already be too late, however, to enable Fort Worth to carry on business as usual, for while the execution order has been hanging over the hospital, staff morale has slipped so badly that 135 of the hospital's usual complement of 400 have either left or retired during the past year, leaving the establishment severely undermanned.

Fort Worth is one of only two federally run narcotics rehabilitation and research centres left in the United States and, like its sister institution at Lexington in Kentucky, it is administered by the Public Health Service. Between them, the two hospitals cater for about 2,000 narcotics addicts each year committed by the District Attorneys' offices under the Narcotics Rehabilitation Act of 1966. Patients are treated at the hospital for a period of about six months and are then sent to an aftercare centre, where they are prepared for return to normal life. In Fort Worth alone, 941 narcotics patients were treated last year.

The thrust of the Administration's policy is to rely less on large in-patient hospitals than on community-based centres. The rationale underlying this approach is that there is more likelihood of success when a patient is treated within his local community, because sending him away to a relatively isolated in-patient hospital causes undue emotional upheaval.

To this end, the National Institute of Mental Health, the agency in charge of the programme, has been setting up community-based treatment centres to cater for patients who would otherwise have gone to Fort Worth, and the intention was to transfer the Fort Worth hospital to the Bureau of Prisons on October 4 for use as a medium security facility for treatment of geriatric, alcoholic and drug addicted prisoners. Opponents of this plan have, however, criticized the Administration for providing inadequate facilities in the community centres to take up the overspill from Fort Worth, and they therefore point out that the plan will simply result in closure of drug rehabilitation munity centres to take up the overspill facilities.

Mr Robert Carrick, deputy director of the NIMH Narcotic Addict Rehabilitation Branch, accepts that more community based facilities are needed, and he pointed out last week that "to say that all are geared up for use is untrue", but he nevertheless suggested that the fifteen centres already in operation have a potential capacity greater than needed to take up the patients from Fort Worth. (The centres are located in Florida, New Jersey, Rhode Island, Puerto Rico, West Tennessee, North Virginia, Arizona, California, Minnesota, two in Mississippi—one of which will serve Kansas—New Mexico, Oregon, Texas and Washington, and there are plans for centres in Louisianna and three more in Texas.)

The centres are operated under contract from NIMH, and the Federal Government reimburses local money spent on the treatment of narcotics addicts under the Narcotics Rehabilitation Act of 1966. Local finance is therefore not a great barrier to operation of a community centre.

Increased capacity notwithstanding, if the Fort Worth facility is closed down, there will be areas of the US that will suffer because they have no local drug treatment facilities of their own. For example, during Congressional hearings on the proposal to set up a Special Action Office for Drug Abuse Control (see page 596), Mr Rogers pointed out that St Louis houses some 6,000 narcotics addicts but that it has only eleven in-patient beds. Similarly, New Orleans has about 6,000 addicts and only ten beds.

For the Administration's plans to treat addicts within their local community to have a chance of working, it therefore follows that drug treatment facilities should be extended to every community in which they are needed, otherwise addicts will still have to be sent away for treatment. This argument is already embodied in legislation introduced into Congress by Mr Rogers and which would prevent payment of grants to community mental health centres after June 30, 1972, unless the grant application is accompanied by assurances that the centre will provide drug rehabilitation facilities.

The legislation is, however, being opposed by the Administration on the grounds that drug rehabilitation facilities may not be needed in every community centre, but even a cursory reading of the Rogers Bill should show that there is just such a get-out clause, for the Bill specifically states that the requirement shall not apply if the Secretary for Health, Education and Welfare "determines that there is not sufficient need for such a program in such hospital or other facility". The Administration therefore seems to be opposing legislation which in effect supports its own position.

The Administration's attempt to close Fort Worth is not an isolated action, for it forms part of a concerted attack on the Public Health Service mounted by almost every successive Administration since the war. So far, Congress has managed to frustrate the present Administration's hatchet wielding against the service, and it looks like being successful in its attempt to keep Fort Worth functioning in its present form for at least another year. The House passed a resolution to that effect earlier this month, and there is no reason to expect that the resolution will be turned down by the Senate.

The House resolution was identical to a resolution passed a few days earlier by the Senate, in that it called for adequate funding for all the Public Health Service Hospitals to allow them to maintain their present functions throughout the present financial year, but the House version also referred specifically to the clinical research centres at Lexington and Fort Worth. The objective of the resolution is to grant a stay of execution to all the eight remaining public health service hospitals so that Congress and the Administration may jointly define a role for them.

Set up in 1798 by the Marine Hospital Act, the Public Health Service hospitals, as they later came to be known, were originally intended for the treatment of American seamen and coastguards. By the end of the nineteenth century, they also discharged some responsibilities in the public health and sanitation fields. The Public Health Service grew slowly in the period up to the Second World War, when it was operating twenty-four hospitals with more than 3,000 beds. Only in the postwar period, when demand for the facilities by American seamen injured in the war slackened off, did the Public Health Service begin to fall foul of the Administration.

All but twelve of the hospitals were closed or converted to outpatient clinics by 1955, and the Budget Bureau was already thirsting after the blood of the survivors, recommending, as it has done ever since, that they be closed. In 1965, the Administration recommended conversion of seven of the smaller hospitals to outpatient clinics, while the Office of Science and Technology recommended that the Public Health Service should continue to operate general hospitals, which should be modernized and given adequate funding.

In the event, only two were closed,

and Congress authorized funds for studies leading to modernization of the remaining ten hospitals. No funds for construction have since been requested, however, and two more hospitals were closed in 1969. The latest attempt to get rid of the Public Health Service came in this year's budget, which simply contained no request for funds to operate the hospitals. The idea was to close the eight Public Health Service hospitals and thirty outpatient clinics, and to turn the Public Health Service Beneficiaries over to the Veterans Administration, severe pressure on the VA's already overburdened facilities notwithstanding.

Although Congress has restored the funds to the Public Health Service, to bring the appropriations up to last year's level, the upshot of the Administration's repeated attacks on the system is that the facilities are rapidly becoming outdated and that the whole system has deteriorated through lack of finance. Repeated recommendations that the hospitals be modernized have been largely ignored, staff levels at the establishments have been allowed to fall and repeated threats of closure have done nothing to stimulate the morale of the Public Health Service's 5,000 doctors. But this deterioration of physical facilities has become one of the Administration's strongest weapons. The pattern is clear: by maintaining the funding for the Public Health Service at minimum levels, the facilities are allowed to deteriorate and the deterioration is later used as an argument for closing the hospitals.

As far as Fort Worth is concerned, there is no doubt that the threat of transfer to the Bureau of Prisons has had a deleterious effect on the staff. As one member said last week, of the 135 who have left during the past year, 85 have retired but expressed their willingness to return if the hospital carries on discharging its present functions.

DDT on Mock Trial

by our Washington Correspondent

A FULL-SCALE public inquiry, billed as the final trial to decide whether or not DDT should be banned from all use in the United States, opened last week in Washington. Chemical manufacturers, in alliance with the US Department of Agriculture are appealing against a cancellation order which the Environmental Protection Agency was forced by federal courts to impose on the pesticide in January this year. Ranged against the Department of Agriculture and the representatives of the chemical manufacturers is the Environmental Protection Agency itself and a variety of environmentalist groups headed by the Environmental Defense Fund.

On the face of things, the hearing could condemn DDT as a hazardous chemical only to be used outside the United States in countries where it is still regarded as an essential weapon in the armoury against malaria. On the other hand, the pesticide could be acquitted and freed for use on certain crops in the United States itself. But the issue is, unfortunately, not that simple. A decision against DDT will in effect only prevent the agent from being sold across state boundaries, and the whole history of the in-fighting and delaying tactics that have accompanied moves to ban DDT in the US shows up the federal pesticide regulatory mechanism for the cumbersome and unsatisfactory procedure that it has become.

Opening shots against DDT were fired in November 1969, ironically by the Department of Agriculture, one of the principal protagonists in the fight to defeat the present cancellation order against the chemical. Amid a blast of publicity, President Nixon then announced that the agriculture department had cancelled four of the existing uses of DDT: spraying tobacco crops and shade trees, use around the home and over water. Thirty days later, however, several producers of the pesticide exercised their rights under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) to request that a scientific advisory committee look into the cancellation order, and thereby set in motion the mills of the pesticides regulatory machinery.

Under the provisions of FIFRA, once an appeal has been filed against a cancellation order, companies are allowed to carry on manufacture and sale of the material under examination. After 1969, pesticide manufacturers were allowed to do this for the seven months that it took for the department of agriculture to set up the appeals committee. Four of the appealing companies withdrew their request for an advisory committee, however, and in July 1970, the Lebanon Company requested a public hearing, but this request was also later withdrawn. What usually happens is that an advisory committee has sixty days in which to file its report, an order either confirming or setting aside the cancellation order is made within ninety days of receipt of the report and sixty days are then available for objections to the second order. An objector has the right to insist on a public hearing on the second order, and a final order is then issued within ninety days of the completion of the public hearing. During the whole proceeding the product can still be legally marketed.

The next step in the campaign against DDT was taken by the Environmental Defense Fund, an environmentalist group, which on October 1, 1969, filed a petition with the Secretary for Agriculture, requesting cancellation and suspension of all uses of DDT. A suspension order would prevent the product from being sold until the whole regulatory process had been completed. This request was, however, ignored for six months, until the Environmental Defense Fund got a court ruling ordering the Secretary for Agriculture to reply, which he duly did, saying that he refused to cancel all uses of DDT. This decision was challenged by the Environmental Defense Fund in the courts.

In the meantime, the pesticides regulatory machinery was taken out of the hands of the Department of Agriculture and placed under the control of the newly-created Environmental Protection Agency, headed by William D. Ruckelshaus. On January 7 this year, a court in Washington DC ordered the EPA to cancel all uses of DDT, and to re-examine the decision not to suspend its use pending a final decision. Ruckelshaus duly cancelled all remaining uses of the chemical on January 15, but after seeking outside advice he decided not to suspend its use. It is that cancellation order which is now being appealed against in the public hearing which opened last week, and which will probably continue into 1972. Nearly two years after the initial moves against DDT, the pesticide is still being legally manufactured and used in the US, chiefly by the Montrose Chemical Corporation and some thirty other companies which buy from Montrose and process DDT for use. Eighty per cent of the DDT manufactured in the United States is exported for use against malaria, however, and this activity is not being contested.

What are the chances that DDT will be acquitted by the public hearing? At present, it is difficult to judge, but protagonists for the chemical will argue that apart from the value of DDT for controlling pests on cotton crops, a decision against the pesticide could have international repercussions which may slow down the eradication of malaria in underdeveloped countries. Already, Dr Marshall Laird, a member of the World Health Organization, has warned the public hearing of this possibility. The hand of the DDT protagonists will also be strengthened by the difficulties in controlling the recent spread of mosquitoes of equine encephalomyelitis in some Southern states. But on the other hand, four government committees which have studied DDT between 1963 and 1969 all recommended phasing out its use, and the Mark commission recommended elimination by December 1971 of all uses of DDT not essential to public health.

NEWS AND VIEWS

Rutherford and Geiger Re-evaluated

ADVANCES in nuclear physics in the past decade have arisen chiefly from developments in instrumentation coupled with the higher energy accelerators that became available in the 1960s. It is more than possible that the suggestion by Dr Peter Rice-Evans on page 625 of this issue of *Nature* will eventually be developed into a technique that will have universal application, although the theoretical predictions have yet to be tested. There are certain to be many Jeremiahs who will deem the idea for a new high energy particle detector as unpractical, but there will be few who will argue that the idea is not worth testing.

Rice-Evans's suggestion is based on the proportional counter concept first developed by Rutherford and Geiger in 1908. The novelty of the present approach is that the proportional counter be used in reverse with the outer cylinder being held at a positive potential with respect to the centre wire. The electrons liberated by the passage of an ionizing particle will thus be accelerated towards the outer cylinder and not towards the centre as in a conventional proportional counter. In this way a pulse with a much faster rise can be expected and the instrument becomes, in principle, a powerful tool that can be used to determine the position of an ionizing particle with a higher degree of precision than is currently possible.

To appreciate the advantages to high energy physics if this detector ever became a practical proposition it only needs to be realized that there is a great deal of current concern that the resolutions currently available with wide plane spark chambers, streamer chambers and multi-wire proportional counters will not be adequate to meet the requirements of the experiments that will be carried out with the new generation of synchrotrons typified by the one being built at Batavia in Illinois, and the 300 GeV machine planned for CERN. The higher energy of the accelerated beam means that the analysed particles will also have a higher energy and will thus suffer smaller deflexions in analysing magnets than particles accelerated in machines of lower energies. There is a need therefore for detectors with good spatial resolution and none of the detectors in current use meets the requirements.

How does the proposed reverse proportional counter supply the necessary high resolution? In such a set up the avalanche produced by an ionizing particle entering the chamber will be outwardly directed, and pulses will only arise in the wire when electrons are liberated near the wire surface in the region of high field necessary for avalanche growth. This is to be compared with a conventional proportional counter where a particle is detected irrespective of where in the chamber the event occurs. The difference emphasizes that the proportional counter was initially designed to maximize the efficiency rather than the spatial resolution as in the present proposed use. The analysis of Rice-Evans shows that a pulse produced by an ion within the critical distance needed to form the avalanche achieves 22 per cent of its maximum height within 10^{10} s of the event occurring. This fast rise is ideally suited for obtaining a fast pulse from a differentiation network to trigger the electronic circuits that are necessary in high energy physics experiments. Thus to obtain a pulse from the chamber an electron must be formed near the wire surface within the critical avalanche radius. It is here that the crucial question of the efficiency of the proposed device arises. To obtain maximum efficiency the radius of the wire needs to be as large as possible, but large wire radius is incompatible with the good spatial resolution that the detector sets out to achieve in the first place. Thus the ever present problem of achieving a compromise between efficiency and resolution would seem to limit the usefulness of the detector.

Calculations by Rice-Evans show that for a typical chamber the region of interaction is limited to a cylinder about the central wire of radius approximately twice that of the wire itself. The efficiency of producing an electron within this region depends on whether the interaction occurs in the wire or in the gas of the chamber, and the probability for these processes is estimated to differ by an order of magnitude—the interaction in the wire being most likely to produce an electron. Thus, the detector radius is effectively the same as the wire radius, and to achieve both high efficiency and high resolution a matrix of many wires will be needed. Such systems are already in use with multi-wire proportional counters.

It is now time to carry out an experimental study with the reverse proportional counter. The problems to be overcome are certain to be many, but only time will tell whether they are insurmountable. Multi-wire proportional counters were first used in 1956, but have only recently achieved universal usage. If the suggested detector is to be used with the new generation of high energy accelerators, however, it has to be developed at a faster pace. The decisions to be made before starting experimental work are many and involve such fundamentals as the material to be used for the wire, what gas to be used in the chamber—or whether a noble liquid could be used instead. The dimensions of the chamber have also to be detected, but of more fundamental importance is the question of how spurious positive ions might affect the performance. Such ions might cause ionization of the gas in the high field region or they might cause secondary electrons to be freed from the surface of the wire. A possible way to circumvent these problems would be to introduce a vapour to neutralize the spurious gas ions and so quench the discharge.

The possibility of the detector being a viable proposition depends entirely on how the expected one to several thousand signal to noise ratio that will arise from particles forming ions outside the avalanche region can be overcome. For a chamber of the dimensions given by Rice-Evans the ratio is one to 5,000 as only 1.5 per cent of the particles will pass through the avalanche region.

The chances of a successful detector being developed in the face of all these uncertainties must be rather small, but several innovations that have in the past seemed to the scientists of the day to have even less chances of developing into viable entities are now accepted techniques. Such a detector or series of detectors must be built and tested.

Earth Sciences Converge in Moscow

from a Correspondent

AT the fifteenth general assembly of the International Union of Geodesy and Geophysics (IUGG) held in Moscow during the first fortnight of August it was clear that at long last, and very belatedly, Earth scientists of various disciplines are beginning to talk each other's language. All interests were catered for at the specialized symposia organized by the various member associations within the union. What follows is a selection of items from some of these symposia; a further report will appear in the forthcoming issue of *Nature Physical Science*.

East Africa, and particularly its rift system, has been the site of major British scientific endeavour for many years and this was evident at the East African Rift symposium where eleven of the contributions were by scientists from the United Kingdom. Eight other countries were also represented and this was the first time so many scientists working in East Africa have gathered together.

Seven speakers dealt with the Afar triangle (the junction of the East African rifts with the Red Sea and Gulf of Aden). The structure of the region was ably reviewed by Mohr (Smithsonian Institution) and the volcanology was discussed by Tazieff (CNRS). On display were two maps of the region, a preliminary Bouguer gravity map by Makris (Hamburg) and a very impressive aeromagnetic map by Hall (Newcastle upon Tyne). Hall's map was coloured in such a way that the quiet zones could be readily distinguished from the regions of large magnetic anomalies similar to those found over the seafloor spreading zones of the Gulf of Aden and the Red Sea. Geologists and geophysicists all agreed that sialic crust must be absent beneath much of this region. This view was confirmed by Jobert (Paris) who described some seismic refraction experiments carried out by dropping bombs in the sea and recording on land in the French territory of Afar and Issas. All his profiles showed the presence of oceanic crust. Only the exact proportion of oceanic to continental crust remains uncertain.

From Afar, the theme of the meeting moved to East Africa. A general review of continental rift zones was given by Milanovsky (Moscow). Knopoff (Los Angeles) then presented evidence which convincingly demonstrated the presence of low seismic velocities beneath the East African rift on the basis of surface wave phase velocities at the Addis Ababa and Nairobi stations. There then followed two geological contributions on the rift volcanics in Kenya; Williams (Nairobi) reviewed the distribution in space and time of the various volcanic rocks, contrasting those occurring on the rift floor and shoulders, and McCall (Victoria) described a special field-geochemical study of the Silali volcano. McCall took the view that the eastern rift is an "aborted" ocean which has never opened up; the rocks are from primary mantle derived material and the magma chambers probably reached to within a kilometre or so of the rift valley floor. Such a view is consistent with the mapping and interpretation of the positive gravity anomaly along the rift axis by Searle (now at Addis Ababa) to which many contributors made reference.

The afternoon session opened with an account by Logachev (Irkutsk) of Soviet expeditions between 1967 and 1969. Soviet scientists have an impressive collection of geological data and have made more than 250 potassium–argon age determinations for 170 different localities in Kenya, Tanzania and Uganda. On the basis of this work, it is thought the process of rifting can be divided into six stages—23–16; 23.5–12; 10–5; 5–2; 2–0.7; and 0.7–0 million years—and each of these represents definite stages of magmatism and structural development. Rykounov (Moscow) described Soviet microearthquake studies in the southern part of the Gregory rift and the northern part of the western rift. In northern Tanzania, he and his colleagues have obtained a crustal structure consisting of 18 km with a P-wave velocity of $5.8\ \mathrm{km\ s^{-1}}$ underlain by 19 km with a P-wave velocity of $6.5\ \mathrm{km\ s^{-1}}$.

Fairhead and Girdler (Newcastle upon Tyne) discussed the relocation of epicentres using the joint epicentre technique. Their plots of epicentres on new fault maps prepared by Baker showed a remarkable correlation between earthquakes and recent geological features. They have also calculated travel time corrections for fifteen siesmic recording stations throughout Africa and have tentatively mapped regions in which P-waves are slowing down beneath the rift system north of the equator. From a study of all available fault plane solutions they suggest that this region is associated with a W.N.W.–E.S.E. stress pattern and with a consequent thinning of the lithosphere.

A notable feature of this meeting on the East African Rift was a consensus of opinion that there must be some separation of the lithospheric plates beneath Afar but none beneath East Africa. It seems that the lithosphere in East Africa has thinned but not broken apart.

At first sight, the choice of ocean floor spreading as a major topic for discussion in an international symposium seems somewhat outmoded, for the major impact of this all-embracing theory came 3–4 years ago and is accepted, in varying degrees, by most Earth scientists. Several speakers dealt with the internal processes that cause the seafloor to spread and the plates to move. Models presented by Turcotte (Cornell) and McKenzie (Cambridge) involved the evaluation of solid state thermal convection as the major driving mechanism. Both suggested that the convective process extends deeper into the Earth than the low velocity layer and that total mantle convection could not be ruled out.

Although much of the ocean floor has been investigated by geophysical methods (one eminent US oceanographic geophysicist bemoaned the fact that there was little of the ocean floor left to study), a group of speakers presented the results of regional studies in localized areas; for example, Talwanie and Pitman (Lamont–Doherty Observatory) discussed the Norwegian–Greenland Sea, Krause and Shilling (Rhode Island) gave an account of the Azores area and Barker (Birmingham) described the active spreading centre in the Scotia Sea.

Although there is now a vast amount of data on the physics, chemistry and shape of the Moon, the "vulcanists" and "impacters" at the symposium on this subject seem to be as widely divided as ever. Those selenologists who proposed an internal origin for the Moon's physical phenomena seemed to be dominant, if only because they were thicker on the ground than their opponents.

Because it is to be replaced by the Inter-Union Commission for Geodynamics, the Upper Mantle Project made its last international appearance in a 4½ day symposium.

The lasting impression of the IUGG assembly is that the next decade should be one of great stimulation and interest as continental geological and geophysical data are reappraised in the light of the seafloor spreading–plate tectonics concept. It is to be hoped that the newly formed Inter-Union Commission for Geodynamics will make a major contribution by guiding these studies.

ADENOVIRUSES

Endonuclease Activity

from our Cell Biology Correspondent

REPORTS of the discovery of this or that enzyme in particles of one or another of the enveloped viruses are these days mundane events, unless, of course, the enzyme happens to be as unusual as reverse transcriptase. By contrast the discovery of enzyme activities associated with the virions of encapsidated viruses is still a comparatively rare event. One such is Burlingham, Doerfler, Pettersson and Philipson's report (*J. Mol. Biol.*, **60**, 45; 1971) that the endonuclease activity which appears in cells infected with adenovirus 2 or 12 and is also associated with purified virions seems to reside in the penton base subunits of the capsids of these viruses.

This new endonuclease activity first came to light when Burlingham and Doerfler (*J. Virol.*, **7**, 707; 1971) were studying the replication of adenovirus 2 and 12 DNA in KB cells and a variety of other permissive and nonpermissive hosts. Burlingham and Doerfler were able to identify three classes of viral DNA in infected cells; molecules which cosediment with DNA extracted from virions and appear to be uncoated parental viral genomes; molecules of adenovirus DNA which are considerably smaller than intact genomes; and finally DNA molecules which are much larger than genomes and may well be parts of the host genome carrying integrated adenovirus DNA. Kinetic studies of the appearance of these three classes of DNA during the course of adenovirus replication lead Burlingham and Doerfler to the conclusion that many adenovirus genomes are cleaved by an endonuclease which appears in the cells after infection and that the cleaved molecules may well be those which are integrated into the host genome. Furthermore, although the experimental details have yet to be published, Burlingham and Doerfler have apparently obtained evidence that the endonuclease is not only a virus-coded protein but also remains associated with pure virions.

Collaborating with Pettersson and Philipson, who with their colleagues at Uppsala have extensively analysed the polypeptides in the three structural units of adenovirus capsids (the hexons, penton bases and penton fibres), Burlingham and Doerfler have tested the capsid subunits for endonuclease activity. Only the penton bases, purified from infected KB cells rather than from pure virions for technical reasons, have this activity, and both selective digestion of the penton bases with trypsin and antiserum to penton base inactivates it. The endonuclease activity is specific for DNA; its activity is twenty-fold greater with native DNA than with denatured DNA as substrate and it cleaves both strands of double-stranded DNA by some "double-hit" mechanism. Moreover, the homogeneity of the cleavage products produced by the endonuclease with adenovirus DNA as substrate suggests it attacks specific sites which are probably rich in G.C base pairs because poly dG.poly dC is a strong competitive inhibitor whereas poly d(AT) has little effect, and actinomycin D partially inhibits the activity. Assuming that penton bases in capsids have the same activity as those extractable from infected cells, Doerfler and Burlingham have provided an interesting example of a viral protein which as well as forming part of a capsid also plays a part in the replication of the viral genome.

Also in the current issue of the *Journal of Molecular Biology* (**60**, 185; 1971) Landgraf-Leurs and Green report their various attempts to exploit the differential binding of synthetic RNAs by the DNA of adenoviruses 2, 7 and 12 for the separation of the complementary strands of these genomes. Apparently poly(U.G) molecules with judiciously selected ratios of U and G bind to different extents to the two strands of these three genomes and separation of complementary strands is possible. To prove their point Landgraf-Leurs and Green report the separation on a preparative scale of the strands of adenovirus 2 DNA and self annealing and hybridization experiments show there is no detectable cross contamination.

PHOTOMORPHOGENESIS

Ach Implicated Again

Gressel, Strausbauch and Galun from the Weizmann Institute provide on page 648 of this issue of *Nature* what may be the first evidence that acetylcholine has a part to play not only in plant photoresponses initiated by red light, but also where blue light provides the stimulus. They have shown that sporulation in the fungus *Trichoderma viride*, which is induced normally

---

Drug Resistance and Ribosomal RNA

ANTIBIOTICS such as streptomycin, spectinomycin, erythromycin and fusidic acid all impair to greater or lesser extents the faithful translation of messenger RNAs in *Escherichia coli*. Resistant mutants can, however, be isolated and, as the pioneering work of Nomura and his associates first established, the loci controlling such resistance specify structural proteins of ribosomes or, in the case of fusidic acid resistance, as other groups have shown, the locus specifying the translocation factor G. But it would be wrong to run away with the idea that mutations leading to resistance to antibiotics which affect translation are confined to genes that specify proteins which are part of the translation machinery. For Helser, Davies and Dahlberg report in next Wednesday's *Nature New Biology* that a mutation which results in resistance to the drug kasugamycin causes a failure in the methylation of 16S ribosomal RNA.

Sparling has shown that kasugamycin interacts with the 30S ribosomal subunit of wild type *E. coli* ribosomes. With the expertise required for the reconstruction of ribosomes from their constituent RNAs and proteins, which has been chiefly developed by Nomura, Helser and his colleagues, at hand at the University of Wisconsin, set about reconstructing 30S ribosomes with proteins and RNAs from either wild type of kasugamycin resistant cells. They quickly discovered that resistance to this drug is not the consequence of a mutated 30S ribosomal protein. They therefore compared fingerprints of the 16S ribosomal RNAs of resistant and sensitive strains, and sure enough found a difference. An oligonucleotide sequence dimethyl-AACCUG present in digests of wild type 16S RNA is replaced by the unmethylated oligonucleotide AACCUG in digests of the 16S RNA from resistant strains. Using RNAs labelled in their methyl groups they confirmed this difference, and further reconstruction experiments proved that resistance or sensitivity to kasugamycin depends on the source of the 16S ribosomal RNA and not on the source of ribosomal proteins.

Apparently therefore the mutation to kasugamycin resistance results in the failure to dimethylate an adenine residue near the 3′ terminus of the 16S ribosomal RNA. Helser *et al.* favour the idea that the mutated locus specifies a methylase responsible for adding the two methyl groups to this adenine residue, although alternative explanations of their findings have not been rigorously excluded. As they note, if the kasugamycin resistance locus does specify a methylase probably more than one species of methylase is involved in methylating ribosomal RNA. For even in the kasugamycin resistant strains the 23S RNA of the large ribosomal subunit is methylated normally.

In short, Helser *et al.* have proved that the function of ribosomes can be altered by mutations which affect ribosomal RNA and they have provided circumstantial evidence suggesting that more than one methylase may be involved in the specific methylation of ribosomal RNA.

by small amounts of blue light, can be initiated by treating the fungus with a mixture of acetylcholine and the acetylcholinesterase inhibitor, eserine.

That acetylcholine, known chiefly for its role in the transmission of nerve impulses in animals, may be active in plant photomorphogenesis is a recent and, on the face of things, bizarre idea. But acetylcholine is known from animal studies to mediate certain processes involving changes in membrane permeability, and it is just these sorts of changes which many plant physiologists believe to be the basis of some aspects of photomorphogenesis.

M. J. Jaffe showed last year that mung bean seedlings not only contain appreciable quantities of a substance which the results of a series of tests suggested strongly to be acetylcholine, but also that the levels of acetylcholine in the plant changed characteristically after exposure to red light. Furthermore, acetylcholine, when given to dark grown seedlings, mimicked the effect of red light in certain photomorphogenic responses. One of these responses was the odd electrical phenomenon discovered by Tanada, where mung bean root tips cling to a negatively charged wet glass surface in red light and release in far-red light (see *Nature New Biology*, **230**, 257; 1971). The implication is that acetylcholine is involved in electrical changes in the plant which presumably follow the photoconversion of phytochrome.

The results that Gressel *et al.* have obtained for *Trichoderma* are not so satisfying as Jaffe's for mung bean, perhaps, but they do imply that there may be a fundamental similarity underlying some red and blue light induced photoresponses. *Trichoderma* sporulates in culture after exposure to blue light but not in darkness. Acetylcholine alone cannot replace blue light in this system, but Gressel *et al.* were able to induce sporulation in the dark using acetylcholine in combination with eserine. The relative amounts needed were specific; sporulation equivalent to 95 per cent of the control value was obtained when 10×10^{-5} M acetylcholine was used with 5×10^{-6} M eserine. Curare, an acetylcholine antagonist, suppressed sporulation in the light control material.

Gressel and his colleagues, however, have not indicated very clearly how they think their data applies to the natural regulation of photomorphogenesis. Is, for example, acetylcholine found naturally in *Trichoderma*, and if so what changes take place after exposure to blue or red light? Does addition of acetylcholine and eserine to the fungus really step round the mechanism controlling sporulation or merely provide the operating factors for altering membrane permeability? The authors tentatively suggest that should acetylcholine prove common to the mechanism of both blue and red light photomorphogenesis, their modes of action will have to be thought out anew. Very true; but these latest results say less about this prospect than raise questions about the basic nature of the changes which lead to sporulation in blue light sensitive fungi.

RHIPIDISTIA

Links with Tetrapods

from our Vertebrate Palaeontology Correspondent

IN the study of the course of vertebrate evolution, one of the most important groups of animals are the extinct rhipidistian fishes. Rhipidistia first appear in the fossil record in the early Devonian and persist into the Permian and it is generally agreed that this group gave rise to all the tetrapods—amphibia, reptiles, birds and mammals. Important information on the anatomy of these forms is contained in two recent articles written jointly by S. M. Andrews and T. W. Westoll (*Trans. Roy. Soc. Edinb.*, **68**, Nos. 9 and 12; 1971).

As would be expected vertebrate palaeontologists have devoted considerable time to the Rhipidistia, but detailed study has been largely confined to description of the skull and speculations about their relationships have been based almost exclusively on cranial anatomy. This is very strikingly the case with *Eusthenopteron*. This fish is known chiefly from the early Upper Devonian of Canada and has been a focus of attention since the early years of this century. The skull is probably better known than that of any other fossil vertebrate, and has been studied particularly by Jarwik who has used the technique of serial grinding originally perfected in Sweden by Stensiö. Although there have been many partial accounts of the rest of the skeleton, a comprehensive, detailed and accurate description of the rest of the skeleton has been lacking, so that the work of Andrews and Westoll on the postcranial skeleton of *Eusthenopteron* is welcome.

In their first article, a description of the paired pectoral fins is accompanied by a detailed analysis of the probable muscle origins and insertions of the fins and shoulder girdle. The resemblance of the proximal part of the fin to the primitive tetrapod limb was already known in general terms; detailed analysis now shows that the range of movements of the early tetrapod humerus is almost identical to that of the first axial element of the fin of *Eusthenopteron*. This part of the rhipidistian fin seems in

Structural Gene of Diphtheria Toxin

IN next Wednesday's *Nature New Biology*, Uchida, Gill and Pappenheimer report an elegant series of experiments which prove that the structural gene for diphtheria toxin is carried by the lysogenic bacteriophage β and some of its close relatives. It has, of course, been known for several years that strains of the diphtheria bacillus *Corynebacterium diphtheriae* which do not make the toxin are rendered toxinogenic when they are lysogenized by bacteriophage β and that the yield of toxin depends on the strain of bacterium and its physiological state. Moreover, the *tox* character of phage β maps at a single locus.

In an attempt to decide between the two alternative explanations of these findings, namely that the *tox* gene specifies the toxin protein or that it regulates the expression of a structural gene for the toxin in the bacterial chromosome, Uchida *et al.* devised an interesting selection procedure which enabled them to isolate a mutant of phage β. Cells of non-toxinogenic strains of *C. diphtheriae* lysogenized by this mutant phage make a protein which cross reacts with anti-toxin antibody but is not toxic and lacks the C terminal sequence of the normal toxin molecule. Clearly, therefore, the *tox* gene specifies the toxin protein itself and the mutation Uchida *et al.* have isolated is either a deletion or a nonsense mutation which prematurely terminates the synthesis of toxin protein.

These findings lead Uchida *et al.* to speculate about the evolution of the *tox* gene. Diphtheria toxin, the substrate of which is restricted to eukaryotic cells, has no role in the replication of phage β and its relatives; it can, for example, be totally deleted without altering the rate of phage replication or the yield of phage. Neither does the toxin have any apparent role in the life cycle of the diphtheria bacillus growing in culture.

Why then has the gene been retained? Uchida *et al.* suggest that the ability to make toxin must have some survival value for the bacillus, and therefore its lysogenic phages, in its natural habitat—the throats of animals and man—and they point out that widespread immunization with diptheria toxoid has resulted in the eradication of toxinogenic strains of *C. diphtheriae* from many human populations. As for the origin of the toxin gene, Uchida and his colleagues speculate that because the only known substrate of the toxin is found exclusively in eukaryotic cells, the toxin gene may have once been a eukaryotic gene which the bacilli or their phage picked up and modified to their own advantage.

fact to be a true tetrapod humerus.

Other resemblances to the anatomy of early tetrapods are also confirmed. *Eusthenopteron* has two-headed dorsal ribs, albeit with very little blade, throughout the trunk. Furthermore, the pelvic girdle probably had a ligamentous attachment to the vertebral column in the sacral region. This condition would be the expected forerunner of the tetrapod sacrum with a bone-to-bone articulation of the girdle to one or more pairs of specialized sacral ribs.

The most interesting differences between the postcranial skeleton of *Eusthenopteron* and those of other rhipidistians, described in the second article, concern the structure of the vertebrae. The vertebrae of *Eusthenopteron*, inadequately described before this account, have been cited in the decades since the war as the ideal forerunners of the tetrapod condition. The other rhipidistians, however, have a bewildering variety of vertebral types, and as more becomes known of the condition in very early, pre-Coal Measure tetrapods the orthodox theory of vertebral evolution in early land vertebrates becomes more and more unsatisfactory.

Description of the skeletons of rhipidistians other than *Eusthenopteron* also allows a more rational classification within the group and one is presented by Andrews and Westoll. These two articles are a remarkable achievement and will long remain an essential source of information for students of vertebrate evolution.

CONTINENTAL DRIFT

Initiation of Rifting

from our Structural Biology Correspondent

KNOWLEDGE of the timing of the opening of the Atlantic Ocean and of the mechanism involved is extremely hard to come by. The lack of clear magnetic anomaly patterns in the "quiet" magnetic zone on both sides of the Atlantic floor has required an extrapolation backwards of spreading rates from the well established younger central zone of the Atlantic in order to gain approximate dates for the opening. This method gives a wide range of dates for the commencement of opening from Late Permian onwards, depending on the spreading rate favoured.

Another method which has been fairly successfully used has been to determine two sets of magnetic pole positions from continental rocks to either side of the Atlantic during successive stages of Earth history from the Carboniferous onwards. By rotating one of these sets of poles by the equivalent of the amount required to close the Atlantic, it is possible to see at what stage the two sets of pole positions fail to coincide, thus giving the first point of Atlantic spreading. Larson and La Fontain (*Earth Planet. Sci. Lett.*, **8**, 341; 1971) found by this method that the Atlantic started to open at the close of the Triassic.

On purely geological reasoning, Hallam (*J. Geol.*, **79**, 129; 1971) suggests that spreading started during Lower to Middle Jurassic at the time of the breakdown to a deeper water environment of the widespread and long-lived carbonate platform of the Mediterranean region. He further suggests that downwarping of the southern North Atlantic borders with associated faulting and volcanic activity during the Upper Triassic indicates a period of rifting occurring some 50 million years before the actual separation of the continents. This model is in good accord with a Rift Valley/Red Sea pattern of oceanic opening.

Further corroboration of Hallam's initial tensional phase before spreading has recently been supplied by May (*Bull. Geol. Soc. Amer.*, **82**, 1285; 1971). He has found that Late Triassic doleritic dyke swarms in eastern North America, West Africa and north-eastern South America fall into a regular radiating pattern if these continents are restored to their relative pre-drift positions (essentially according to the Dietz *et al.* reconstruction (*Bull. Geol. Soc. Amer.*, **81**, 1915; 1970). The pattern is roughly convergent on the Blake plateau, the Bahama platform and the western Senegal basin, and individually the dykes bear no particular relationship to the structures of the continental rocks through which they intrude. It thus seems that the stress field responsible for the dyke intrusions was unrelated to continental crust tectonics but rather, as the dolerites themselves are of typical oceanic composition, to activity within the upper mantle.

May is able to show that the intrusion of the dykes was related to a tensional

The Extent of Reverse Transcription

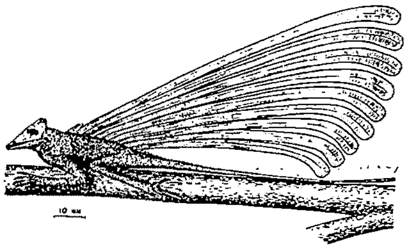
IT is hard to believe that the chief role of reverse transcriptase in tumour viruses is something other than the synthesis of a double stranded DNA provirus as Temin has proposed. And Duesberg and Canaani have already reported, as expected, that the reverse transcriptase in Rous sarcoma virus transcribes *in vitro* all the sequences present in the viral RNA genome, albeit as a series of small DNA molecules rather than a single DNA molecule as big as the viral genome. In next Wednesday's *Nature New Biology*, however, Varmus, Levinson and Bishop describe a more detailed analysis of the products of reverse transcription of Rous sarcoma RNA which suggests that at least *in vitro* some sequences of the viral genome are preferentially transcribed into double stranded DNA.

Reverse transcription takes place in two steps; the first is the synthesis of a single DNA strand complementary to the viral RNA genome to yield a RNA.DNA hybrid; the second involves the synthesis of a double stranded DNA using this hybrid as template. When Duesberg and Canaani measured the extent of transcription *in vitro* of Rous sarcoma virus RNA they hybridized the total DNA, made, both single and double stranded, to viral RNA.

What Varmus *et al.* have now done is measure the extent of reverse transcription *in vitro* into double stranded DNA. After separating the single stranded from double stranded DNA made by Rous sarcoma virus reverse transcriptase they measured the rates of reassociation, after denaturation, of the double stranded product. Most of this DNA rapidly reassociated, a small proportion slowly reassociated and some failed to reassociate. By making various assumptions Varmus *et al.* estimated the molecular weight of the rapidly reassociating fraction and what fraction of the total Rous sarcoma genome it corresponds to. They claim that from 85–90 per cent of the double stranded DNA is probably transcribed from about only 5 per cent of the viral genome assuming its molecular weight to be 10×10^6.

But does the slowly reassociating fraction of the double stranded DNA contain sequences corresponding to the entire viral genome? Varmus *et al.* claim, from measurements of the rate at which it reassociates, that this double stranded DNA corresponds to only about 20 per cent, rather than 100 per cent of the genome. Moreover, they report experiments which they interpret as showing that at least 30 per cent of the DNA sequences found in RNA.DNA hybrids are not transcribed further into detectable amounts of double stranded DNA. They mention, however, unpublished experiments of Martin and his colleagues who apparently also find a major rapidly reassociating fraction and a smaller slowly reassociating fraction of double stranded product but who believe the smaller population of molecules include all the sequences of the complete viral genome. It is perhaps too early to decide which interpretation is correct, but it seems clear that a small part of the viral genome is transcribed *in vitro* into double stranded DNA much more often than into the complete genome.

Triassic Glider



THIS illustration shows a reconstruction of the lower Triassic reptile, *Longisquama insignis*, the remains of which were recovered by A. G. Sharov of the Soviet Academy of Sciences in the river clay deposits at Fergami in the Turkestan Ridge, 60 km from Leninabad (*Priroda*, No. 7, 108; 1971). The spinal appendages in this pseudosuchian were plate-like and were arranged in pairs down the spine. In addition to the skeleton, Sharov also found the scaly cover of the body and extremities.

phase affecting a broad area of crust before the drifting of the continents. He constructed two-dimensional stress trajectories (orthogonal lines representing variation in maximum and minimum stress directions) by drawing lines normal to the dyke trends (minimum stress) and lines parallel to the dyke trends (maximum stress). From these trajectories it is not only possible to determine surfaces of regional tension but also surfaces of regional shear and it was these surfaces that were later utilized to form the spreading axis of the Atlantic. The continental margins of North America north of the Bahamas and of West Africa north of Senegal broadly follow tension lines as does the southern coast of West Africa off Liberia. But from the Ivory Coast west to Nigeria the continental margin follows a direction of shear possibly related to the Romanche fracture zone.

Furthermore, the stress trajectories show a concentration of stress in an area around the Bahamas Ridge—a point not made by May but apparent from his construction. This concentration of stress in the upper mantle resulted in the tensional phase over a wide area of the overlying crust with the consequent dyke intrusion in the Late Triassic. At a later date the continental crust split, possibly initially at the point of stress concentration and subsequently along incipient lines of tension and shear. With the onset of rifting the stress on the continent was relieved and further displacements of the mantle resulted only in the production of new oceanic crust in the rift.

SENSORY PHYSIOLOGY

Olfaction and Taste

from a Correspondent

MOST of the research discussed at the fourth international symposium on olfaction and taste, held at Starnberg, Munich, between August 2 and 4, illustrated the progress which has been made in the understanding of the morphology and electrophysiology of single sensory cells or sensory epithelia, with relatively little emphasis on the central processing of chemosensory information or the influence of chemical stimuli on behaviour.

To elucidate the transduction mechanism by which chemical stimuli induce electrical changes in cells, it is convenient to be able to obtain reasonably large quantities of receptor membrane for analysis of the composition and conformation of the receptor surface. Dr J.-P. Changeux (Institut Pasteur, Paris) has used cell fragments of the electroplaque of the electric eel as a bulk preparation of cholinergic receptors and has been able to extract protein fractions which seem to bind acetylcholine, carbamylcholine and decamethonium.

The ubiquitous *Escherichia coli*, which is also readily available in bulk, has been used by Professor J. Adler (University of Wisconsin) to investigate the molecular basis of chemotaxis. Several species of receptor molecule on the receptor surface of the bacterium interact selectively with one of a group of substances to influence the direction of movement of the organism.

In spite of the difficulty of preparing pure extracts for analysis, sugar binding proteins from the sensory cells have been identified in cow tongue by Dr M. Sato (Kumamoto University) and in rat tongue by Dr K. Hansen (Zoologisches Institut, Heidelburg). In some particularly small scale experiments with blowflies, Dr H. Morita (Kyushu University) has found α-glucosidase activity associated with single contact receptor endings. Much more work will be needed, however, before it is understood how such interactions may be associated with changes in the ionic permeability of sensory cell membranes. Dr U. Thurm (Ruhr University, Bochum) has demonstrated that part of the total potential difference across insect sensory epithelium is dependent on metabolic energy. No further evidence was presented, however, to

Skiddaw Slates and Borrowdale Volcanics

THE rocks of many areas have been greatly faulted and cleaved as a result of Earth movements following their deposition. Over the years much geological work has been carried out in the Lake District, as elsewhere, to unravel the types and ages of Earth movements which have disturbed the country rocks. At the base of the stratigraphical succession of the sedimentary rocks of the Lake District are the Skiddaw Slates, of Ordovician age, on which rest the Borrowdale Volcanic rocks, also considered to be Ordovician. These in turn are succeeded by the Coniston Limestone Group (Ordovician) on which lie the Silurian flags, grits and shales.

The junction between the Skiddaw Slates and the overlying Borrowdale Volcanic rocks has been variously described as conformable, an unconformity, or faulted. A considerable obstacle to a confident opinion on this problem is the rarity of clear sections of the junction, because the surface of the country is widely covered by glacial and other drift deposits.

The Coniston Limestone Group succeeds the Borrowdale Volcanic rocks and it is now widely thought that the junction between these two groups of strata is markedly unconformable.

A thick succession of shales, flagstones, grits and greywacke lie above the Coniston Limestone Group and these belong to the Silurian System. These beds are succeeded with marked unconformity by the local representatives of the Old Red Sandstone (Devonian) or Carboniferous Limestone Series.

Recent wide scale mapping, involving the collection and plotting of large numbers of dips, strike lines and faults, suggests that the structure is more complicated than previously supposed. In particular, the relationship between the Borrowdale Volcanic rocks and the underlying Skiddaw Slates has been examined in great detail where exposed, but opinion still differs as to whether the junction is conformable, unconformable or faulted and, if the last-named, the nature of the faulting involved. Some workers, indeed, claim to recognize six groups of minor structures in the Black Combe area which, together with south-west Cumberland, Borrowdale (Keswick) and Cross Fell, has recently been re-examined.

In next Monday's *Nature Physical Science*, Helm and Roberts describe in detail the latest information about the Skiddaw Slate–Borrowdale Volcanic junction. But there is still much doubt about the detailed succession and the faulting and folding in the Skiddaw Slates.

clarify the issue of whether energy amplification is necessary at some stage in chemosensory transduction. Many of the speakers implied that it is, and this is clearly a crucial problem.

The low threshold for the response of many insect antennae to sex attractants is now well known. Dr R. A. Steinbrecht (Max Planck Institute für Verhaltensphysiologie, Seewiesen) explained how the silk moth antenna collects molecules of sex attractant, bombykol, and how these molecules reach the receptor cell membrane, and Drs K. E. Kaissling and G. Kasang (also of Seewiesen) discussed its remarkable isomeric specificity and its ability to resolve brief pulses of sex attractant applied in series. The properties of this receptor mechanism are rivalled in specificity by those of the antenna of the moth *Plusia ni* in response to its sex pheromone, cis-7-dodecenyl acetate. Dr L. K. Gaston (University of California, Riverside) spoke of the enormous differences in responses by this preparation when stimulated by different isomers of the compound, and similar ones of differing hydrocarbon chain length. Other speakers, including Dr J. Jakinovich (University of Michigan, Ann Arbor) on fly chemoreceptor specificity in response to different isomers of inositol, and Dr W. A. Kafka (Seewiesen) on the relative responses of locust olfactory cells to different isomers of methylbutanoic acid, revealed astonishingly narrow specificities. But few clues have emerged about the structure of the receptor sites for any of these pheromone molecules.

Studies were also presented on aspects of response characterization of sensory cells of vertebrate nasal and lingual epithelia, on the innervation of these cells, and on the way in which their responses may be influenced through intravascular stimuli. Perfused cyclamates can generate responses which summate with those to sweet tasting substances applied externally to the rat tongue (Dr R. M. Bradley, Nuffield Institute for Medical Research, Oxford). Another interesting study presented by Dr B. Oakley (University of Michigan, Ann Arbor) indicates that sets of taste papillae of the rat tongue, which show similar response characteristics, become associated with branches of the same afferent nerve fibre. This may imply that nerve fibres growing out into the tongue "search for" and recognize papillae of similar specificity pattern.

The proceedings of the symposium are due to appear in a volume of collected papers in about six months time, and it was agreed that the next symposium in this series would be held in Melbourne, Australia, about three years hence.

THE EARTH

Chondritic Again

from our Geomagnetism Correspondent

THE idea that the principal minor element in the Earth's fluid outer core may be sulphur rather than either nickel or silicon—and thus that the Earth as a whole may be chondritic after all—has now received further substantial support from Hall and Murthy (*Earth Planet. Sci. Lett.*, **11,** 239; 1971). This thesis, which Murthy and Hall propounded last year (*Phys. Earth Planet. Interiors,* **2,** 276; 1970) on the basis of an analysis of the relative abundance of volatile elements in the crust and mantle, was more recently taken up by Lewis (*Earth Planet. Sci. Lett.*, **11,** 130; 1971) who adduced several pieces of indirect evidence for it and discussed in some detail its important consequences. But Lewis's admitted difficulty was the lack of the thermodynamic data needed to make the case really convincing. It is this deficiency which Hall and Murthy have now remedied to a limited extent.

The classical view of the formation of the Earth's core is that an iron–nickel mixture segregated from a silicate matrix. It is Hall and Murthy's contention, however, that the first melt to form during the early history of the Earth was an FeS–Fe eutectic. These different processes are clearly likely to have different effects on the distribution of elements throughout the Earth and thus imply different courses for the Earth's subsequent history. So how would the elements be distributed if an Fe–S liquid had separated to form the Earth's core? In an attempt to answer this question Hall and Murthy have taken seventeen "diagnostic" elements, including the alkali metals Li, Na, K, Rb, and Cs, the alkali earths Be, Mg, Ca, Sr, and Ba, the transition metals Mn and Fe, and other critical elements such as Cu, Zn, U, Th, and Pb, and have tried to determine thermodynamically how they would become distributed between a predominantly Mg–Fe silicate matrix and an Fe–S melt during the Earth's early history.

As a starting point Hall and Murthy present thermodynamic data for the simple reaction $MeO+FeS=MeS+FeO$ where Me is an electropositive element. It is quite clear from the table they have compiled that K, Rb and Cs have high negative free energies of reaction at both 298 K and 1,000 K and thus preferentially form sulphides. These data thus support Lewis's contention that if an Fe–S liquid segregates into the core it will take with it a great deal of the available K, Rb and Cs, so that these elements will accordingly be depleted in the crust relative to a chon-

The Micro-friction of Graphite

NEW frictional studies of graphite at low loads (1 to 400 mg) have revealed much greater differences between the coefficient of friction of the basal and edge planes than expected. In next Monday's *Nature Physical Science,* Skinner, Gane and Tabor report their measurements of the coefficient of friction, using a scanning electron microscope and a delicately loaded tungsten stylus with a tip radius of about 1 μm.

They have found that the coefficient of friction on the edge plane is between fifteen and sixty times greater than the coefficient measured on the basal plane (0.3 compared with about 0.005 to 0.02); this is a much larger anisotropy than has been measured previously. Skinner *et al.* suggest that this is because their experiment involved not only small loads but also almost perfect surfaces which were carefully selected under the electron microscope.

At loads less than 40 mg, the low coefficients of friction of the basal plane were usually accompanied by only slight surface damage and, in some cases, by no damage at all. Sometimes the cleaving of a flake was observed as in the figure and very occasionally a peeling action took place; this was associated with much higher coefficients of friction (about 0.4).

At greater loads the basal planes were often too weak to support the stylus and even when they did, the stylus was found to penetrate further and further into the specimen until the experiment had to be stopped.

dritic composition. On the other hand, it would be unrealistic to suppose that such a simple reaction is applicable to the whole Earth and thus that the oxide-sulphide equilibrium is anything but vaguely indicative of real conditions. This view is supported by the data. For example, sodium can also be seen to possess a high negative free energy of reaction, which fact would suggest that sodium was also withdrawn into the core and correspondingly depleted in the crust. But this is patently not so.

As Goldschmidt pointed out many years ago (in *Geochemistry*, Clarendon Press, Oxford, 1954), different reactions are applicable to different parts of the Earth. Thus Hall and Murthy go on to consider more appropriate equilibria. For the crust they examine reactions of the type $MeSO_4$ with FeS and $MeCO_3$ with FeS, which are consistent with the typically high oxidation states of crustal material. By contrast, for the mantle, which at the time of Fe–S segregation would have been in a reducing environment, the corresponding reactants with FeS are of the type $MeSiO_3$ and Me_2SiO_4. For each of the seventeen elements and for each reaction Hall and Murthy have computed heats of reaction (which dominate the free energies of reaction).

The results are striking. Elements like Be and Th (and thus by implication U) are strongly lithophilic under both crustal and mantle conditions. By contrast, elements such as Cu, Hg, Ag, Pb and Zn are strongly chalcophilic under crustal conditions and remain so throughout the mantle. But the critical elements K, Rb and Cs which are strongly lithophilic under crustal conditions rapidly change to being chalcophile under mantle conditions. In the presence of an Fe–S liquid these elements would thus have been drawn into the liquid and thus into the core. Sodium, on the other hand, remains lithophilic in the primitive mantle—and so the anomaly implied by the oxide–sulphide equilibrium disappears. In short, notwithstanding the fact that the reactions considered must be oversimplified compared with those applicable to the real Earth, the thermodynamic data obtained by Hall and Murthy are consistent with known abundances of the relevant alkalis in the crust and mantle.

As Hall and Murthy admit, however, this apparent success conceals some real objections. For example, their calculations have been made for an aluminium-free system ; and it is well known that Na and K have different terrestrial relationships with Al. Under crustal conditions both Na and K form alumino-silicates, especially felspars. But in the mantle, where pressures are higher, felspars are unstable and change to denser phases such as jadeite, the Na alumino-silicate. Potassium, on the other hand, does not apparently produce a high pressure form equivalent to jadeite for Na. If such a form really cannot exist, that fact alone may account to some extent for the different behaviours of Na and K in mantle regions. Ignorance of mantle conditions at the time of core formation precludes any detailed assessment of the role of Al at present, although, whatever the cause, the difference in behaviour between Na and K seems established. And further support for it comes from crystal chemistry. Potassium (and Cs and Rb) ions are larger than Na (and Li) ions and are thus less likely to fit into the mantle pyroxene structure but more likely to be absorbed into an available liquid. Thus Hall and Murthy suggest that "the incompatible nature of K, Hb, and Cs which has been reflected in their selective enrichment into basaltic melts through geological time must also be reflected in their enrichment into an Fe–S liquid during core formation in the early history of the Earth".

The distribution of elements implied by the early existence of an Fe–S melt, and, in particular, the removal of K into the core, would, of course, have affected the Earth's thermal history—and this implies that many conventional thermal models of the Earth must be revised. The apparent near-constancy of K/U ratios for a variety of terrestrial rocks has led many people to suppose that such a ratio (about 1×10^4) is a fixed feature of the Earth, the critical variable being the original total radioactivities in various parts of the Earth. But what Hall and Murthy have done is to show that this assumed "coherence" between K and U is not necessarily valid and that, on the contrary, it is quite possible that K separated from U (and Th) during the early history of the Earth.

Finally, the fact that Rb behaves like K in the presence of an Fe–S liquid would explain why Rb/Sr ratios in the Earth's crust are lower than chondritic. In short, if Hall and Murthy are right about the presence of an Fe–S melt during the early history of the Earth, the principal objections to the chondritic Earth are apparently removed.

Dynamic Stereochemical Model for ATP Synthesis

THERE have been many models of the mechanism by which chloroplasts and mitochondria can utilize redox energy associated with electron flow for photo and oxidative phosphorylation. In recent years the chemiosmotic scheme and chemical hypothesis (see Greville in *Current Topics in Bioenergetics* (edited by D. R. Sanadi, **3**, Academic Press, New York and London, 1969) have commanded the most attention. These schemes, however, tend not to deal with the detailed molecular processes which must be involved.

In next Wednesday's *Nature New Biology*, A. Bennun presents an hypothesis which attempts to relate molecular conformational changes within proteins with the process by which electron flow gives rise to ATP synthesis. He considers that the proteins involved in the energy transduction are coupling factors isolated from either chloroplasts (CF_1) or mitochondria (F_1) which show ATPase activity under appropriate conditions. These factors are thought to undergo dynamic stereochemical reactions induced by electron transport which involve charge dependent conformational changes.

Bennun has used kinetic data from chloroplast studies (Bennun and Avron, *Biochim. Biophys. Acta*, **79**, 646 ; 1964) to produce a scheme which involves two stages. The first stage is the formation of a proton dependent electrostatic complex, which is produced, it is argued, when an electron carrier, closely associated with CF_1 or F_1, is reduced. Because of the change in electric field the redistribution of the electrons within the coupling factors produces new dipolar forms. This complex, however, is not thought to be capable of directly inducing phosphorylation until the second stage, which is brought about by a loss of a proton and the dissipation of the partial charges within the protein. Bennun argues that the disappearance of the dipolar structure of CF_1 or F_1 leads to the formation of a phosphorylated high energy intermediate which then gives rise to ATP. The formation of these complexes is suggested to occur within the membrane which, as Bennun points out, would tend to result in structural restriction of the conformational changes associated with charge redistribution. Such restrictions could then act as effective energy sources.

Bennun takes his model one step further in attempting to explain the mechanism by which membrane located ATPase catalyses the hydrolysis of ATP and utilizes the energy for active transport of ions. Essentially the reverse process to that already described is thought to occur. The protons released could conceivably conserve their energy by binding to the relevant proteins which may be the ATPase itself or some other membrane protein. This binding could induce conformational changes involving stretching dipoles similar to that suggested for the coupling factors, and may occur as a result of changes in the degree of hydration of the protein.

Supermassive Objects in Astrophysics

VIRGINIA TRIMBLE
Institute of Theoretical Astronomy, Cambridge.

The scientific interests of William A. Fowler cover an unusually wide range. The symposium held at the Institute of Theoretical Astronomy, Cambridge, on July 19 to 21, 1971, in honour of his sixtieth birthday was designed to explore some of the topics with which he has been concerned and the relasionships among them.

IT was the extraordinarily large amounts of energy needed to explain radio sources and quasars that first led Hoyle and Fowler[1,2] and Hoyle, Fowler, Burbidge and Burbidge[3] to suggest that single objects much more massive than stars might be important in astrophysics. Since then, supermassive stars have been in and out of fashion several times as sources of energy and sites of nucleosynthesis, each time motivating a variety of theoretical studies and suggesting new ways of looking at observational data. Speakers at the symposium repeatedly emphasized the importance of the interplay of observations, theory and laboratory experiments in shaping our understanding of massive objects as well as ordinary stars and the processes occurring in them.

Black and White Holes

In accordance with the Fowler dictum of always searching for the objects with the largest possible binding energy, a session was devoted to collapsed configurations. The work of Penrose[4,5], Israel[6], Carter[7] and Hawking (to be published) has led to a picture of gravitational collapse in which the formation of a closed, trapped surface (roughly, one from which no light ray or other signal can ever escape to infinity) is followed inevitably by the formation of a singularity in the curvature of space–time. This singularity is probably shielded from view by a horizon, forming a "black hole", although the existence of what Penrose calls naked singularities cannot be excluded. Their work has also shown that space–time outside the singularity probably comes to look (asymtotically as time goes on) like either the Schwartzschild solution or the Kerr solution to Einstein's field equations. These solutions are characterized respectively by the mass of the singularity and by its mass and angular momentum. The singularity may also be charged but all other properties (lepton number, baryon number, multipole moments of the electromagnetic field and so forth) are probably lost or radiated away during the collapse. Thus, in the words of J. A. Wheeler, a black hole has no hair.

B. Carter (University of Cambridge) reviewed recently proven theorems directed towards changing the probabilities in the above picture to certainties. Not all loopholes have yet been closed.

S. Hawking (University of Cambridge) has shown[8] that there is a limit to the fraction of the mass energy of a singularity that can be radiated in all forms from a collision with another singularity. This limit is always less than 50%. Thus black hole collisions cannot be a 100% efficient source of gravitational radiation in a particular bandwidth, even if each object is involved in a series of collisions. This increases the amount of mass that must be involved in producing the pulses of gravitational radiation reported by Weber[9].

Despite the horizon surrounding a Kerr-type singularity, it is possible to extract that part of its energy associated with rotation rather than rest mass. J. A. Wheeler (Princeton University) suggested this as one of the most promising ways of finding observational evidence for black holes. (Searches for gravitational lens effects produced by them, X-rays resulting from matter accreting on them, gravitational radiation emitted at their formation, and binary systems with black hole components have also been proposed, and in some cases attempted.) Wheeler considered the fate of a white dwarf or neutron star falling into the neighbourhood of a black hole of mass $\sim 10^5\ M_\odot$. Tidal forces may fracture the star into two or a few pieces in that region known as the ergosphere (where the dragging of inertial frames by the rotating singularity is so rapid that no particle can remain at rest as seen by an observer at infinity). Then (as discussed by Penrose[10] for a single incident particle) while one fragment falls into the singularity, another can come out with more total energy than the incident star originally had. About 30% of the total mass-energy of a black hole with the maximum possible angular momentum for its mass could be extracted in this fashion.

W. D. Arnett (Rice University and Cambridge) provided a certain amount of discouragement by reporting a series of calculations of the late phases of evolution of a star of mass 30 to 100 $M_\odot$. In no case was a dense remnant left which was significantly larger than the Chandrasekhar limit for stable white dwarf stars. Thus only if the upper limit to neutron star masses is smaller than that for white dwarf masses would any of these remnants ever collapse to a black hole.

White holes are the time reversals of black holes, that is, mass energy expanding out of a singularity. They can thus provide literally unlimited amounts of energy. The apparently complete arbitrariness of the time at which the expansion starts was partially responsible for the lack of enthusiasm for white holes expressed by many of the symposium participants.

Supermassive Stars and Disks

The relativists participating in the symposium clearly regarded collapse to a singularity as a desirable event. The astrophysicists, on the other hand, were principally concerned with preventing supermassive stars from collapsing, or at any rate from collapsing too quickly, so that their energy could be extracted in some useful form. The problem is that there are, once one has taken relativistic effects into account, no stable, cold, slowly rotating configurations for masses greater than one or two $M_\odot$. And even the "hottest" configuration of a spherical supermassive star burning nuclear fuel is not stable against collapse above about 10^6 $M_\odot$—whether the star is assumed to be static or undergoing relaxation oscillations. Possible additional sources of support to balance gravitation in still larger objects are magnetic fields and rotation. The latter is particularly useful: there is no limit to the amount of mass that can be put into an infinitely thin, rotating disk. The problem in this case is that the disk seems to fragment into a number of small objects, and this process and subsequent events are very difficult to calculate. F. Hoyle (University of Cambridge) and E. Salpeter (Cornell University) each reviewed a probable "life history" of a supermassive object from formation to fragmentation and/or ultimate collapse.

Very massive stars may have formed out of the general interstellar medium early in the history of the galaxy, but this does not seem to be occurring at the present time. The most likely (or at any rate least unlikely) point of origin for a supermassive star now is at the centre of a galaxy or star cluster. Here, the gas lost by stars (either peacefully or through supernova explosions) will collect and condense, provided it can dissipate enough of its angular momentum. If the gas falls in sufficiently quickly, creating turbulence, dissipation of its dynamical energy will heat the gas and raise its entropy. If opacities are high enough to trap all the energy, pressure will suffice to support a spherical equilibrium configuration (which may or may not be stable) of mass up to 10^8 $M_\odot$. Slower collapse will lead to a rotating disk because the entropy of a given mass of interstellar medium is not as great as that of a spherical supermassive star of the same mass.

The supermassive star continues to lose energy by radiation and to contract. Its centre heats up and, for masses up to 10^6 $M_\odot$ (if there is no rotation) or 10^8 $M_\odot$ (for the maximum amount of uniform rotation), nuclear reactions "turn on" before the star reaches the critical radius at which its binding energy ceases to increase making collapse inevitable.

I. Appenzeller and K. Fricke (University of Göttingen), R. Talbot (Rice University and Cambridge) and R. Tayler (University of Sussex) presented results of calculations of nuclear burning in stars of mass 100 to 10^7 $M_\odot$. The German group finds that the relaxation oscillations proposed by Fowler[11] will probably occur and prevent collapse in stars of masses $\gtrsim 0.75 \times 10^6$ $M_\odot$. The star first contracts: Its central temperature and density, and thus the rate of nuclear energy generation, increase rapidly until the star is lifted back out again and the energy generated is released as thermal and non-thermal radiation and kinetic energy of matter blown off. The star then contracts again and so forth. The oscillation period is about one year, which might be relevant to periodicities perhaps observed for quasars. Objects more massive than 10^6 $M_\odot$ will not have their collapse halted by this process.

For stars with masses of 10^2 to 10^3 $M_\odot$, R. Talbot and Papeloizou (University of Sussex) find that pulsational instability almost certainly does not blow the star apart because pulsation energy is dissipated in shock waves and fed into stable harmonics of the unstable fundamental mode. Rather, material seems to be lost gradually. As this process continues, layers are lost which were previously in the star's convective core. They thus contain material in which nuclear reactions have occurred. Stars of this type early in the history of the galaxy, could have contributed an appreciable fraction of the helium as well as heavier elements we now observe. (Stars less massive than 50 $M_\odot$ or so appear to contribute very little helium.)

These objects can yield, at best, 0.01 of their rest mass energy in useful form, because that is the limit of efficiency of nuclear processes. To do better, we must consider more condensed configurations, whose binding energy is a significant fraction of Mc^2. Because of the collapse that sets in, for a massive spherical object below $r \sim 3 \times 10^5 \left(\frac{M}{M_\odot}\right)^{3/2}$ cm (where the binding energy is still $\ll Mc^2$), this means considering a rotating disk or a dense swarm of smaller objects.

The binding energy of a uniformly rotating, thin disk—most of the results thus far obtained will carry over to differentially rotating disks—increases monotonically with its degree of compactness to a maximum of about 0.37 Mc^2 at the point where the redshift of light from its centre is infinite[12,13]. Such a disk is therefore probably stable against overall gravitational collapse and thus useful for astrophysical purposes.

J. Bardeen (University of Washington) discussed the optical appearance of such a disk. As it contracts, it develops an ergosphere from which energy can be extracted. The effect of the rapid rotation on photons emitted is roughly to blueshift those emitted in the forward direction of the rotation and redshift those emitted in the backward direction. This effect is superimposed on the gravitational redshift produced by any massive object. Thus, although some photons are received at infinity with a blueshift, the total luminosity of the object goes to zero as the redshift from its centre goes to infinity. Light from the disk has a unique redshift only if it is uniformly rotating and seen face on. Most of the photons which reach a distant observer are, however, emitted in the equatorial plane of the disk, making such a disk by itself unpromising as a quasar model.

A. G. W. Cameron (Yeshiva University) discussed the probable behaviour of a gas disk inside a dense star cluster. The winding up of magnetic field lines by differential rotation may lead to the ejection of jets of material along its rotation axis by a mechanism analogous to that found by Leblanc and Wilson[14] for supernovae. Second, even a small amount of gas in this form can turn cosmic ray energy into thermal radiation very efficiently. Finally, accretion of the gas onto stars, by raising their masses, may appreciably enhance the supernova rate in the cluster.

Contributions by F. Pacini (Frascati) and by L. M. Ozernoi and V. V. Usov (Lebedev Institute, Moscow) dealt with massive rotating objects with magnetic fields. These might be expected to exhibit behaviour somewhat like that of pulsars, which somehow convert rotational energy to a useful form very efficiently. Some rough analogies between the properties of quasars and those of the Crab Nebula add interest to this type of model.

The contraction of a mass of 10^9 $M_\odot$ from an initial radius of 10^{21} cm, initial rotation period of 3×10^8 yr, and initial magnetic field strength of 10^{-5} to 10^{-6} gauss (reasonable properties for the centre of a galaxy) to a radius of 10^{16} cm yields a rotation frequency $\Omega \sim 10^{-7}$ s^{-1} and a magnetic field strength $B \sim 10^4$ to 10^5 gauss if angular momentum and magnetic flux are conserved. The rotation energy of such an object is $\sim 10^{60}$ erg and its magnetic energy $\sim 10^{56}$ erg. The magnetized disk then radiates by non-thermal as well as thermal mechanisms[15,16], contracts, and speeds up its rotation.

If the dominant form of energy loss is by magnetic dipole radiation at the rotation frequency, or particle ejection, then the luminosity of the object increases as $(1-t/t_0)^{-4/3}$ and its rotation frequency increases as $(1-t/t_0)^{-1/2}$. Such low frequency electromagnetic radiation cannot, of course, propagate in any reasonable surrounding medium, but there is, in any case, of order

$$L = 10^{47} \left(\frac{B}{10^5}\right)^2 \left(\frac{R}{10^{16}}\right)^6 \left(\frac{\Omega}{10^{-7}}\right)^4 \text{ erg s}^{-1}$$

of energy made available in some form. L may be decreased by a factor $\sin^2 \theta$ if magnetic and rotation axes are not perpendicular.

The time dependence of the luminosity is more complicated if there are other important energy losses or if the magnetic axis gradually becomes aligned with the rotation axis but the observed number of quasars, active galactic nuclei and the like as a function of luminosity is not inconsistent with the prediction of even a simple model. The luminosity of the disk stops increasing and drops rapidly to zero as seen by an observer at infinity when the disk has shrunk to such an extent that relativistic effects become important.

R. Wagoner (Cornell University and Cambridge) discussed the fate of the electromagnetic moments of a disk having a distribution of azimuthal currents and charges (such that the net charge of the disk is zero) on it, when the disk collapses as a result of the extraction of angular momentum from it. The magnetic dipole and octapole and electric quadrupole moments all appear to vanish as $(Z_c+1)^{-2}$ as Z_c, the redshift of light coming from the centre of the disk, goes to infinity. There is no reason to believe that other multipoles will not do the same. Thus, only visible objects seem able to radiate by the pulsar mechanism.

A black hole continues to exert a gravitational force on the outside world and thus can have a rotating disk around it, made up of material which either did not collapse or was accreted after the collapse. Lynden-Bell has considered such disks as the energy sources for quasars and galactic nuclei[17,18]. Viscosity in the disk will cause the gas to spiral gradually into the black hole. By the time a particle reaches the last stable orbit outside the black hole, it will have lost 42% of its rest mass energy at infinity. This is the most efficient way of extracting energy from ordinary matter so far found.

The thin, uniformly rotating disk considered by Salpeter, Bardeen and Wagoner[12,13,19] seem to be stable against collapse (though not, of course, against contraction as they radiate energy away). They are not, however, stable against fragmentation. Although gravitational forces are balanced by rotation and thermal forces (gas and radiation pressure) for the disk as a whole, gravitation predominates strongly for a piece of the disk having a size much greater than the thickness of the disk but much less than its radius, when this piece is considered by itself. As the disk loses energy, it becomes flatter, and, when it reaches an axial ratio of 0.05 (for a uniformly rotating disk), it will probably break into two or a few pieces. These, in turn, radiate away energy and flatten until they are unstable to breakup, and so forth.

Although the swarm of fragments continues to occupy about the same volume as the original disk did, they are individually much denser than it was. Thus binding energy has been extracted from them. Each generation of fragments is able to radiate the same fraction of its total energy. In many generations, the process can therefore become quite efficient.

The smaller objects will differ from the original disk in having higher equilibrium central temperatures, so that nuclear burning will turn on at some point, delaying the contraction and fragmentation of the blobs. They will also be increasingly efficient emitters of magnetic dipole radiation (provided some magnetic field was initially present) if total angular momentum and magnetic flux are conserved as they fragment. Gravitational radiation will also become increasingly important as fragmentation progresses if the mass distribution maintains its asymmetry.

There are many complications in this process, for example, variations in the angular momentum distribution, possible collisions of blobs, possible recoalescence of blobs, dissipation of angular momentum by viscosity, dissipation of asymmetries in the mass distribution by gravitational radiation, and possible ways of extracting the thermal energy of the gas. It is just possible that the fragmentation could end in a swarm of (essentially) mass points whose gravitational potential is sufficiently flat at the centre to produce a fairly constant gravitational redshift from a central gas cloud, thus permitting objects with large redshift to be closer to us than their cosmological distances, as suggested by Fowler and Hoyle[20].

F. Hoyle (Cambridge) pointed out that, despite the wide range of phenomena possible in this scheme in which objects proceed toward more and more condensed states, it may not suffice. We may yet have to consider matter evolving through expansion especially to explain violent events in galactic nuclei and the formation of large double radio sources.

Observations

The need for large amounts of energy ($\sim 10^{62}$ erg) to account for the observed properties of radio sources first suggested to Hoyle and Fowler that supermassive objects might be important in astrophysical contexts. Observations since that time have, with about equal frequency, suggested new theoretical approaches to the problems of quasars and galactic nuclei and created difficulties for old ones.

G. Burbidge (University of California, La Jolla) and R. Weymann (Arizona) reviewed some of these problems, ranging from very general questions of energetics to specific difficulties, such as whether or not emission line profiles of Seyfert galaxies can be understood in the context of a gas disk rotating around a condensed central mass.

A compilation of the various kinds of radiation and mass loss which we see going on[21] suggests that the release of gravitational energy in the nuclei of galaxies may be the most important source of energy in the universe. Some more or less continuous process must be involved, since nearly all nuclei show a degree of activity. This continuous activity might be easier to understand as the result matter expanding from, rather than contracting to, a condensed state or singularity.

It also appears difficult to explain the ejection of coherent, massive objects from galactic nuclei on the basis of the conventional contraction hypothesis (although either Wheeler's ergosphere mechanism or ejection of bits of Salpeter's fragmented disk could impart large velocities to bodies of mass $\lesssim 1\ M_\odot$). Among possible evidence for such massive coherent ejecta are tiny radio source components far from their parent galaxies (including those in Cygnus A, ref. 22), the bright optical blobs in the jet of M87, and the Seyfert-like galaxies VV 144 and I Zw 95 which are connected by jets or bridges to nearby, smaller, more normal looking objects. On a less spectacular scale, asymmetries and transient doubling of Seyfert galaxy emission lines can be attributed to the ejection of blobs of gas of mass 0.1 to 1.0 $M_\odot$ with velocities of 1,000 to 5,000 km s^{-1}.

Actual or potential observations can also have a bearing on whether a single, supermassive object or a swarm of smaller ones is more likely to be responsible for active nuclei. Genuine periodicity in the variations of the brightness of quasars and so on would be strong evidence for a single, coherent rotating object (although differential rotation is likely to shear off a "hot spot", so that a given pattern of variability would only last for a few periods[23]). The large amplitudes of quasar light variations already suggest that one or a few objects are responsible for most of the continuum light output at a given time. A series of radio outbursts along the same axis or a single outburst involving more than $\sim 10^{52}$ erg (the binding energy of a neutron star) would also be evidence for a single object. A single, supermassive magnetic rotator might be detectable as a low frequency, very small radio source in the way that the Crab Nebula pulsar was first seen[24]. Finally, an outburst from a single central object might be expected to disturb and blow away the thermal gas cloud which produces the emission lines in an active nucleus. The Seyfert galaxy NGC 3516, in which a broad Hβ line disappeared sometime between 1942 and 1967 (ref. 25) and reappeared between 1967 and 1969 may have done something of the sort.

In 3C 120, on the other hand, the broad hydrogen lines appear not to have been disturbed by the sharp radio outbursts which have occurred in the past few years. This would seem to be evidence for a group of smaller objects, only one of which blew up (or perhaps for a single object with strong directivity). If successive violent events in a number of small objects are responsible for the luminosity of a small, bright Seyfert nucleus like that of NGC 4151, then the centre of light ought to move around. This also applies to the radio positions of unresolved quasars.

The amount of energy and mass required to explain violent

Pure Chemistry Library

activity in quasars and galactic nuclei depends, of course, on their distances. Distances to peculiar objects are measured either by direct application of the Hubble–Lundmark relation or from their physical association with other objects whose distances we think we know. The problems arise when these conflict. For ordinary galaxies, selected by some appropriate luminosity criterion, the redshift–magnitude relation is fitted extremely well by a straight line. For quasi-stellar objects, on the other hand, it is a scatter diagram[26]; thus we lack strong evidence that redshift is a measure of distance for these objects.

Several cases have been found in which two objects with different redshifts appear to be connected by bridges, jets or arms. These include NGC 4319+MK 205, NGC 7603+ a nearby compact galaxy, and IC 1746+ an adjacent quasi-stellar object. In other cases (for example, VV 172 and Seyfert's Sextet) objects with different redshifts are not connected but are clustered at least in the plane of the sky. Finally, Burbidge, Burbidge, Solomon and Strittmatter (to be published) have found that four of the 3C quasars are within 6′ of spiral galaxies in de Vaucouleur's catalogue. Only 0.2 such close association would be expected by chance. On the other hand, one or more QSOs appear to be associated with normal galaxies having the same redshift[27]. Some of the participants were sufficiently impressed to express the view that conventional physics may be inadequate to explain these data.

The optical continuum of an active nucleus should reveal something about the objects producing it; if we see the surface of a supermassive star or disk directly, then the continuum spectrum ought to be basically thermal whereas a non-thermal spectrum would imply that the energy of the central object is being transformed into relativistic particle and magnetic field energy.

As observed, the optical continuum of active objects typically looks non-thermal. It may, however, be necessary to correct the continuum for the reddening found by Wampler[28] for Seyfert emission lines. This will be the case if the material producing the lines covers all or most of the continuum source. After making such a correction, Pagel (Royal Greenwich Observatory) and Kaneko[29] find that the emitted spectrum in fact looks like the Rayleigh–Jeans part of a thermal continuum, with $T \gtrsim 60{,}000$ K, rising into the ultraviolet.

As for line spectra, Seyfert and Markarian type nuclei are easier to understand than QSOs. The galactic nuclei typically show relatively sharp forbidden emission lines and hydrogen Balmer lines with sharp cores and much broader ($\Delta V \sim 5{,}000$ km s^{-1}) wings. Along a sequence from Seyfert galaxies to QSOs, the ratios [OIII]/Hβ and Hβ (core)/Hβ (wings) tend to drop (to zero in some cases).

Photoionization appears able to account for all the lines observed in Seyfert nuclei, as the presence of [FeXIV] in NGC 4151 has not been confirmed[30]. The forbidden lines are necessarily produced in a low density region, while the broad Balmer lines are most easily understood in terms of a combination of electron scattering in dense, small cores ($N_e \sim 10^8$ to 10^9; $R \sim 10^{16}$ cm) and ejection of line-radiating blobs at velocities of 1,000 to 5,000 km s^{-1}. A model with rotational broadening due to an optically thin disk rotating around a central mass $\gtrsim 3 \times 10^8\ M_\odot$ is also possible, but only a very narrow range of parameters can account for the observed profiles. No abundance anomalies are required to explain Seyfert galaxy line spectra, but abundance variations by factors of 2 or 3 are quite possible.

In quasars, on the other hand, no model appears to account satisfactorily for the line profiles. If resonance lines are trapped efficiently enough to yield the observed widths, then they should be strongly self-reversed. And sufficient gas motions to smear out the self-reversal would also make the forbidden lines broad.

As far as abundances are concerned, it is still not clear whether the weakness of helium recombination lines relative to those of hydrogen in 3C 273 is an abundance effect. It might, rather, be due to a low degree of helium ionization[31]. A better upper limit to, or detection of, HeI (5876 Å) would resolve the question.

Objects like NGC 1068, whose Balmer lines do not have broad wings, may have had their dense gas swept out by violent events at their centres. If the events take the form of ejection of relativistic particles, Rayleigh–Taylor instability at the particle–gas interface would produce filamentary structure like that seen in NGC 1275. The gas would also be given the sorts of velocities found in transient line doubling and would eventually produce larger regions of more tenuous gas. These are seen (with diameters ~100 pc) in Seyferts and perhaps in QSOs if the relatively sharp QSO absorption lines are produced in the objects themselves.

We may be observing one object in transition between the broad, supernova-like absorption bands seen in PHL 5200 (ref. 32) and the sharp absorption lines, often at several very different redshifts, seen in other QSOs. The object PHL 957 (ref. 33) has an emission redshift of 2.679 (as measured on Lick spectrograms; E. M. Burbidge, private communication) and at least eight separate absorption redshifts. One of these is represented by extremely broad Ly α and Ly β lines at $Z=2.308$. This is the largest difference so far found between an emission and an absorption redshift for broad lines, and neither the large ΔZ nor the broadness of the lines can be understood in terms of intergalactic absorption. The object is thus evidence for a high velocity explosion in a high density region of the QSO.

Nucleosynthesis and Reaction Rates

The rates of nuclear reactions are crucial to the determination of what nuclear fuels are burned, at what temperatures and densities they burn, and what the reaction products are, both in supermassive and ordinary stars. C. A. Barnes (California Institute of Technology) pointed out that the completeness of our knowledge declines rapidly with increasing atomic weight of the reactants. All the cross sections needed to deal with hydrogen burning seem to be well established but at the other end of the scale, it is not even obvious what nuclear information is required in order to treat silicon burning. The abundances of the products of silicon burning may, in some cases, depend on nuclear reaction rates and, in others, on equilibrium considerations and binding energies.

In the intermediate range, after the conversion of hydrogen to helium, the next nuclear reactions in stars are (*a*) the combination of three alpha particles to form carbon-12, (*b*) the addition of another alpha particle to form oxygen-16, and (*c*) successive heavy ion reactions to form neon-20, magnesium-24 and so on. Since it appears that the rates of the reactions of type (*c*) are much slower than (*a*) and (*b*), the relative abundances of carbon and oxygen depend almost exclusively on the rates of (*a*) and (*b*). Recent information[34–36] (and unpublished work by Barnes, Dyer, Kavanagh, Mann, McCaslin, Morgan, Nichols, Thompson and Weisser at California Institute of Technology) leads to the conclusion that the time is rapidly approaching when a comparison of the observed carbon to oxygen ratio with that predicted from laboratory measurements will provide a critical test of prevailing theories of helium-burning nucleosynthesis. At the same time, the carbon–oxygen ratio at the conclusion of helium burning appears to be of great importance for later, explosive stages of stellar evolution, possibly even determining whether or not a remnant is left after such an explosion or supernova.

A knowledge of the nuclear reactions that occur in stars of various masses and the birth rates of these stars as a function of time in the Galaxy could be combined to give the history of the nuclear composition of the Galaxy provided we knew how much of each star is thrown back into the interstellar medium for reuse and how much is trapped in white dwarfs, neutron stars, and black holes. Calculating this history therefore requires three input parameters, all of which are extremely uncertain; nor are the data on stellar compositions as a function of age and position in the galaxy, with which the calculations are to be compared, as well established as we would like. Nevertheless, such calculations have been attempted by W. D. Arnett (Rice University and Cambridge) and A. G. W. Cameron (Yeshiva University) and their colleagues. The two groups have made rather different assumptions, especially about the fractions of a star going into the various possible reaction products (unprocessed hydrogen + proton enriched nuclei, helium, carbon and oxygen, iron, neutron enriched nuclei, white dwarfs, neutron stars and black holes). Each group has succeeded in matching the observations of metal abundance as a function of stellar age. Cameron has also taken account of the constraints on the production of heavy nuclei provided by solar system data on the abundances of radioactive nuclei and their decay products. Arnett's work also reproduces the distribution of stellar abundances as a function of position in the galaxy.

Insight is provided by these calculations into some details of observed stellar abundances. For instance, the systematic tendency of the ratio N/Fe to be very low whenever Fe/H is low (B. Pagel), follows from the fact that nitrogen is largely produced in CNO cycle burning of hydrogen, which requires that carbon and oxygen have been produced in a previous generation of stars. Thus no nitrogen is formed until the second generation.

It is necessary in these nucleosynthesis calculations to assume that a larger fraction of star forming material went into massive stars in the past than it does now. Otherwise, according to Cameron, almost 25% of the one solar mass stars now seen would have metal abundances less than 10% of the solar value, which is not the case. Thus galaxies should have been much bluer and much brighter in the past.

There is, however, some observational evidence that the birthrate function, $\Phi(M)$, does not change its shape as a function of time. W. L. W. Sargent (California Institute of Technology), L. Searle, and W. Bagnuolo have found that the present *UBV* colours of Irregular and Sc galaxies can be understood in terms of a birthrate function given by $\Phi(M,t)=A(t)M^{-n}$. If a typical galaxy is 10^{10} yr old, then $n=1.35$ for Sc and 1.1 for Irregular type galaxies. For the bluest galaxies of each type, $A(t)$ has been essentially constant, whereas for the reddest ones (for example, Magellanic Cloud type Irregulars), $A(t)$ is now about 0.1 of its value 10^{10} yr ago.

Even at the present time and for our own Galaxy, $\Phi(M)$ is not well known, especially for very high and very low masses. The power law M^{-n}, must cut off (for $n>1$) below some minimum mass; otherwise the integral mass involved would be infinite. Where this cutoff occurs is important because low mass stars lock up both processed and unprocessed material and prevent it from taking further part in galactic nucleosynthesis. Because objects with $M \lesssim 0.1\ M_\odot$ never burn hydrogen, they are almost undetectable except as astrometric companions to nearby dwarf stars (for example, Barnard's star). This means that the low mass cutoff may be unobservable. The very massive stars, which contribute the largest fraction of heavy elements, are also a problem. N. J. Woolf (Minnesota) noted that the brightest (and therefore presumably most massive) single star known (6 Cyg No. 12, $M_{\mathrm{bol}} \lesssim -10$) is hidden behind a dense envelope, seriously hampering our determination of the space density of such stars. A large, wide field telescope in the southern hemisphere should make it possible to determine the birthrate function for stars more massive than 1 to 2 $M_\odot$ in the Magellanic Clouds where the effects of dust obscuration are much less severe than in the Galaxy.

Finally, it is not even clear that our Galaxy is a closed system as assumed in all calculations of galactic nuclear evolution. It is quite possible that the clouds of neutral hydrogen considered by Oort[38,39] to be falling into the galactic plane at high velocities represent intergalactic matter being added to the interstellar medium at a rate of 0.1 to 1 $M_\odot$ yr^{-1}. Such matter would presumably consist of only hydrogen and perhaps helium and would thus significantly dilute the heavier elements produced in stars.

Concluding Remarks

A number of problems remain, particularly in understanding how supermassive objects are formed. Nor is there yet any really firm observational evidence for their existence. But when supermassive stars were first proposed as a source of large amounts of energy, they seemed to be pulsationally unstable. Subsequent work, some of it discussed at this symposium, has shown that this is probably not the case. Thus we are perhaps justified in joining the Fathers of the Subject, Hoyle and Fowler[40], in turning a blind eye, a deaf ear, and a cold shoulder to written, oral and implied criticism respectively.

We thank Drs M. J. Rees, W. L. W. Sargent, R. V. Wagoner, S. W. Hawking, E. M. Burbidge, G. Steigman and W. D. Arnett for comments; the speakers who supplied preprints or outlines of their talks, and especially Professor William A. Fowler for starting it all.

South Labrador Sea and the Evolution of the North Atlantic

A. S. LAUGHTON
National Institute of Oceanography, Wormley, Godalming, Surrey

Basement morphology and magnetic anomalies in the South Labrador Sea have preserved the history of the changes from a two-plate configuration of sea floor spreading to a three-plate configuration after the split between Greenland and Rockall Plateau and back to a two-plate configuration when the Labrador Sea stopped widening.

BEFORE the separation of Rockall Plateau and North-West Europe from Greenland and the growth of the Reykjanes Ridge, the Labrador Sea was the northern part of the Atlantic Ocean. Although it is floored by sediments[1,2] which almost totally obscure the basement topography except south of Greenland, a buried mid-ocean ridge has been located beneath the sediments by seismic and magnetic methods[2-6]. The identification of the magnetic anomalies on the Heirtzler time scale[7], and hence the history of the sea during the Mesozoic and Tertiary has, however, been uncertain[2,6,8].

This article reports a new interpretation of the South Labrador Sea based on data obtained during leg 12 of the Deep Sea Drilling Project in D.V. Glomar Challenger and earlier data.

Basement Morphology

Fig. 1 shows what is now known of the basement in the southern Labrador Sea, and includes some features typical of seafloor spreading, such as mid-ocean ridges, median valleys and transform faults. At 57° N, 48° W, Le Pichon *et al.*[2] have identified a buried median valley which is consistent with the magnetic data in the area. Further east, at 57° N, 43° W, two lines of basement ridges are separated by an east–west valley filled with sediment, which appears to be a median valley paralleled by magnetic anomalies[9]. On this meridian, this is the only place between the Gibbs Fracture Zone and Cape Farewell where the basement topography suggests a spreading centre (see Fig. 11 of ref. 10). The adjacent ridges both seem to have been uplifted and tilted away from the axis preserving a sediment cover of 0.2 s on their outer flanks. These two sections of median valley are not colinear and are separated by a broad ridge complex about 70 km wide striking north-east–south-west. The ridge can best be interpreted as a fracture zone or transform fault offsetting the axis of the median valley. The strike of the transform fault is in general agreement with the pole of rotation of 61° N, 92° W calculated for the last phase of the opening of the Labrador Sea by Le Pichon *et al.*[2].

South of Greenland, Le Pichon *et al.* found basement ridges which they interpeted as a transform fault (the Farewell Transform Fault) associated with the first phase of opening of the Labrador Sea. Further south, they also associated the buried part of the Gibbs Fracture between 45° and 47° W with this phase, and from these two features the pole for the first phase of opening was computed to be at 80° N, 89° W.

The remaining structural trend is normal to the west end of the Gibbs Fracture Zone, and is perhaps truncated by it, suggesting that the ridges on this trend are the remains of structure parallel to the spreading axis during the first phase of opening of the Labrador Sea. Magnetic analyses indicate that the ridges may be the extinct spreading axis. Further north-west, the ridge at 55.7° N, 48.5° W, is parallel to the median valley to the north of it and probably belongs to the second phase of opening.

All the basement trends in Fig. 1, except the exposed part of the Gibbs Fracture Zone, can be correlated with either the spreading axes or transform faults associated with the two phases of opening of the Labrador Sea. The Gibbs Fracture Zone[11] east of 43° W is associated with spreading about the Mid-Atlantic Ridge further east.

The semicircle formed by the basement ridges has been a barrier to deep water circulation and the transport of sediment. It encloses a large body of sediment typified by topographic

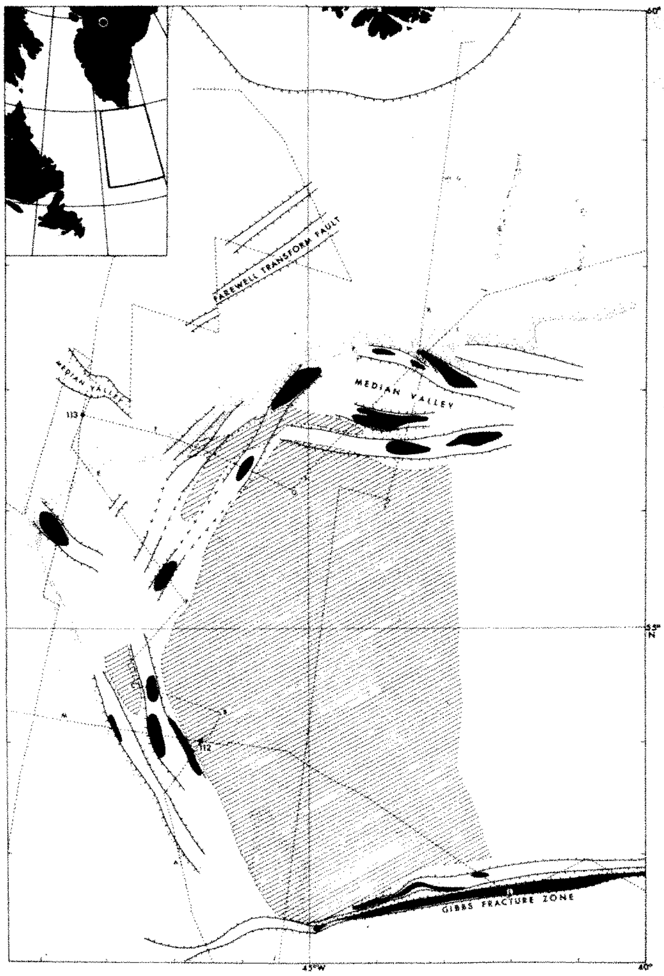

Fig. 1 Basement structure and sediment cover of the South Labrador Sea derived from seismic reflexion profiles and from bathymetry. Ticked lines = basement scarps; dense hachure = basement exposures on sea floor; stippled boundary = contact between terrigenous sediments and bottom current controlled sediment body; light hachure = area of oligocene mid-sediment reflector.

ridges several hundred kilometres long, a wavy surface, marginal channels and moats, and no conformity with the basement. It is relatively transparent except for a mid-sediment reflector (shaded in Fig. 1) shown by drilling to be Oligocene. These characteristics suggest that the sediments were laid down under the influence of the near bottom currents[8,10,12] and the pattern of ridges indicates an anticlockwise bottom circulation fed from the east through the Gibbs Fracture Zone. From the extent of the reflector and the conformity with it of overlying beds, the deep circulation in the southern Labrador Sea seems to have remained relatively constant since the mid-Tertiary in spite of the considerable change in width of the Atlantic.

Some of the sediments have overflowed the basement barriers and to the west and south are lying underneath the terrigenous sediments which have accumulated at a high rate due to the proximity of land and which were sampled at site 113; their extent is shown in Fig. 1 by the stipple boundary. Another sedimentary supply by ocean currents along the south-east coast of Greenland gave rise to the Eirik Ridge[12] which lies above the Farewell Transform Fault. Contrary to the suggestion of Jones *et al.*[10], this does not seem to be related to the sediment body at 55° N, 45° W.

Magnetic Data

There is a symmetrical pattern of magnetic anomalies, which trends north-west–south-east in the Central Labrador Sea and east–west south of Cape Farewell[1,2,4–6,9,13,14], offset by two fracture zones trending north-east–south-west. The axis of symmetry in the central Labrador Sea is magnetically smooth, but two groups of high amplitude anomalies (500 gamma peak-to-peak) lie halfway between the axis and the continental slope. South of Cape Farewell, the southerly group of these anomalies bends sharply southwards parallel to the Mid-Atlantic ridge. At 52.5° N they are offset eastwards by the Gibbs Fracture Zone. The interpretation of the tectonic history of the Labrador Sea depends critically on the age of these anomalies and of the axis.

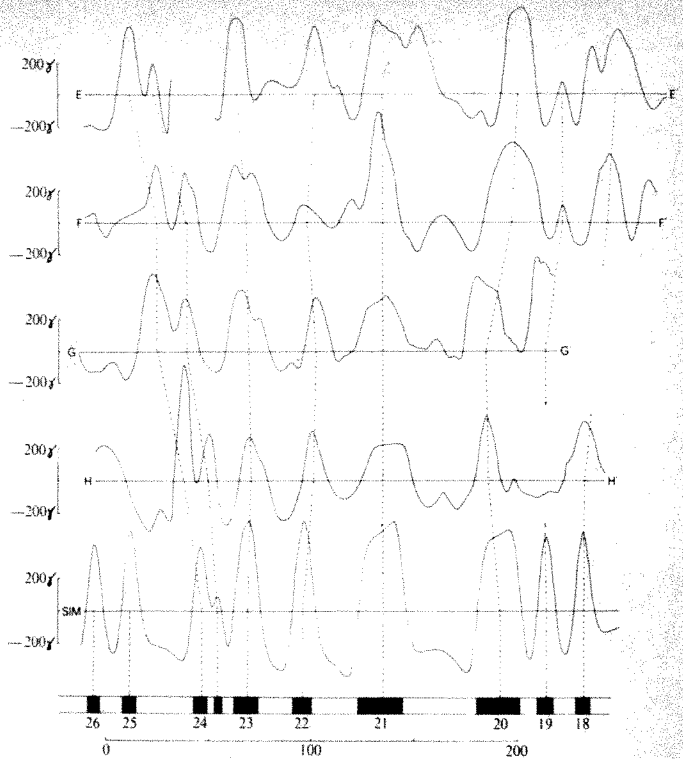

Fig. 3 Magnetic anomalies along tracks EE′, FF′, GG′ and HH′ (Fig. 2) projected perpendicular to anomaly trend 170°, compared with simulated anomaly using Heirtzler *et al.*[7] time scale for anomalies 18 to 26. (Magnetized layer 4.5 to 6.5 km below sea level; effective susceptibility ±0.01 c.g.s. units; black blocks normally magnetized. Spreading rate of 1.26 cm yr^{-1}.)

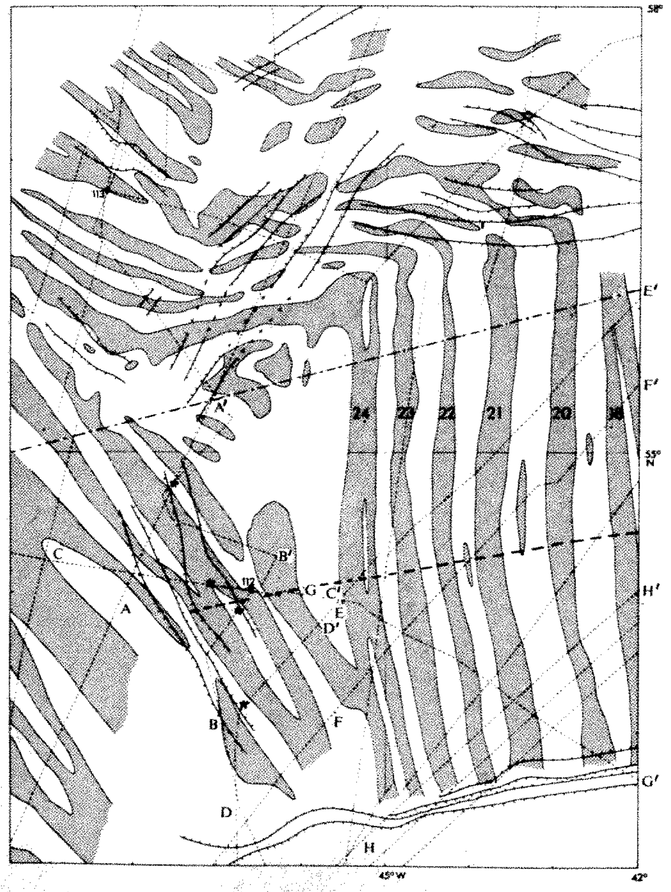

Fig. 2 Magnetic anomaly chart of South Labrador Sea. North of dot-dash line, contours are modified from Vogt *et al.*[15]. South of this line, control is by tracks shown. Shaded area is positive. Anomaly numbers are from Fig. 3.

In the South Labrador Sea, the magnetic anomalies (Fig. 2) relate closely to basement trends and reflect the various phases of opening of the Labrador Sea and the North Atlantic. North of 56° N, the contours (modified from Vogt *et al.*[15]) show the trends parallel to the median valleys, and the symmetry about them, and the offset due to the transform fault. The strong north–south lineations between 42° and 45° W can be matched with a simulated anomaly pattern for anomalies 18 to 24 (ref. 7) with a spreading rate of 1.3 cm yr^{-1} parallel to the Gibbs Fracture Zone (Fig. 3). Some dislocation of this pattern may, however, be present along the heavy dashed line in Fig. 2, which is a westward continuation of the fracture zone crossing the Mid-Atlantic Ridge at 53.5° N (ref. 16).

West of 45° W, the magnetic anomaly pattern trends north-west–south-east, parallel to the basement ridges near site 112. The correlations in this area are less certain than the north–south ones, but the trend is clear and continues to the north-west into the area of better mapped anomalies in the Labrador Sea. Near site 112, the lack of continuity may be due to the fracture zone. The same north-west–south-east trend is repeated towards the south-west as far as the continental margin. Further evidence of a change of pattern west of anomaly 24 comes from the absence of anomalies 25 and 26 on the projected profiles in Fig. 3. A triangular area centred on 55° N, 46° W, for which there are no data, is enclosed by the three prominent trends.

Data Interpretation

We can now follow the evolution of the northern part of the North Atlantic with some certainty by working backwards using the above magnetic data together with other magnetic data from several sources (refs. 14, 17–20 and data from the USNOO) and the fracture zones (Fig. 4). The principal fracture zone controlling the North Atlantic opening is the Gibbs Fracture Zone, known also as the Charlie or 53° N Fracture Zone (refs. 11, 16, 21 and data from the NIO and the USNOO). South of this are numerous fracture zones offsetting the ridge axis to 28° W and indicated by earthquake epicentres. These have been lumped together as one fracture zone at 50° N.

The symmetry of magnetic anomalies 19 to 24 about the Mid-Atlantic Ridge between 53° and 56° N confirms the identification of the north–south anomalies south of Greenland. The continuity of anomaly 20 between a north–south orientation and an east–west orientation at 56.5° N, 43° W (Fig. 2), its proximity to the median valley, and the apparent absence of such a right angle for anomaly 19, suggests that the Greenland and Labrador plates have not separated appreciably since anomaly 19 (47 m.y. ago). On this assumption, the European plate can be closed into the Labrador–Greenland plate using the Gibbs Fracture Zone as a control guide to give the 47 m.y. (Middle Eocene) palaeogeography (Fig. 5). A good fit of anomaly 19 is obtained. A consequence of the immobility of Labrador–Greenland plate boundary after 47 m.y. is that the median valley south of Cape Farewell should not extend further east than 41.5° W; this can be tested by further surveys.

Before 47 m.y., Greenland and Labrador have to be closed along the lines indicated by the fracture zones offsetting the Mid-Labrador Sea Ridge axis, while the closure of the Reykjanes Ridge still continues. The anomaly 24 or 60 m.y. (Palaeocene) palaeogeography (Fig. 6) differs slightly from that presented by Vogt *et al.*[9] in the greater counterclockwise rotation of the European plate. Rockall Plateau, shown by holes 116 and 117 to have subsided from above sea level since the Palaeocene, is not close up against the continental slope of Greenland at this time although anomaly 24 is very close to Rockall Plateau. The original Greenland continental margin may, perhaps, have been downwarped after the breakaway of Rockall Plateau or else an Upper Cretaceous geosynclinal sedimentary basin may have existed before the split. In the central Labrador Sea, the two prominent magnetic anomaly groups are apparently older than 60 m.y.

At 60 m.y., the whole anomaly pattern changed from the two plate geometry because of the separation of the European plate from Greenland. All magnetic anomalies older than 60 m.y. have a trend more north-west–south-east than those of 60 m.y. and younger. These trends were directed parallel to the Labrador continental margin and approximately parallel to that of the Greenland–European plate margin. The most prominent of these trends are those near site 112 which are now median to the Palaeocene ocean and offset from the central Labrador Sea anomalies by the Farewell Transform Fault and its counterpart on the Labrador margin[2]. This transform fault may be part of the line of weakness continuing north-east into the region between Rockall Plateau and Greenland which subsequently split to give the Reykjanes Ridge. The anomalies near site 112 and the associated basement ridges may be part of the fossil ridge axis resulting from the final phases of the pre-Palaeocene spreading which took place before a shift of stress pattern occurred beneath the plates. The initiation of spreading between Rockall Plateau and Greenland profoundly modified the geometry by the introduction of a triple junction and switched the spreading axis near site 112 from north-west–south-east to north–south.

If this theory is correct, the age of the seafloor near site 112 should increase towards the north-east, up to the angle of anomaly 24, and the magnetic anomaly pattern across the ridge should be symmetrical. Some profiles, projected at right angles to the ridge, are presented in Fig. 8. Some crude symmetry can be seen about an axis between two positive peaks. Only profile AA′ is long enough without course alterations to test the symmetry in detail beyond the positive peaks. The symmetry axes are indicated in Fig. 2 by asterisks, and do not lie in a straight line along the ridge. Either the detailed contouring of the ridge (both by basement topography and by anomaly) is wrong or there are undetected fracture zones offsetting the old axis.

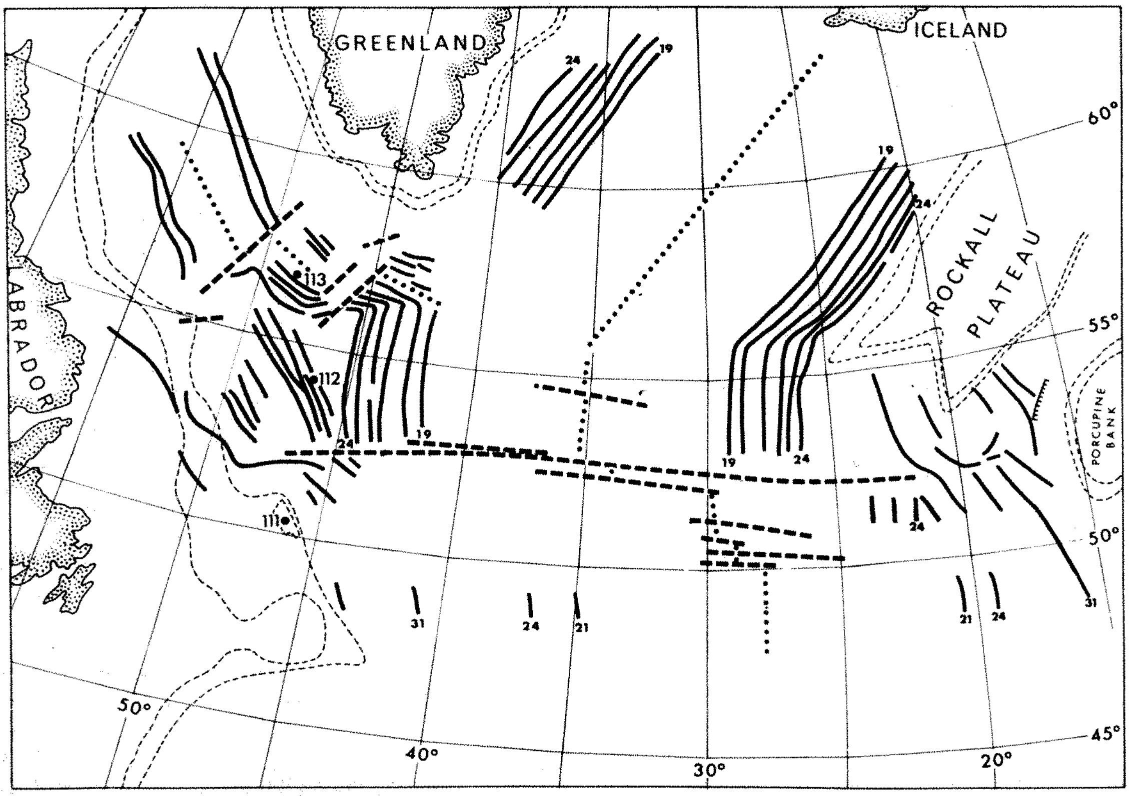

Fig. 4 Magnetic anomaly trends in the North Atlantic. - - -, Top and bottom of continental slope; ———, positive magnetic anomalies from number 19 and older; — — —, fracture zones; . . ., present and extinct spreading axes.

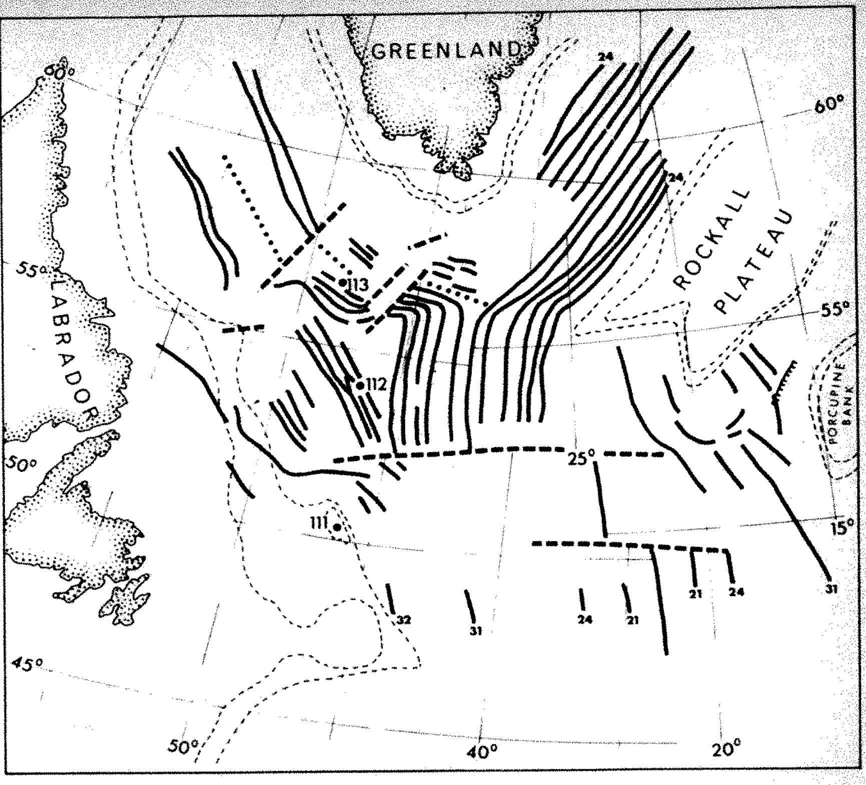

Fig. 5 Palaeogeographic reconstruction at anomaly 19 (47 m.y., Middle Eocene).

The age of the basement sampled at site 112 is calculated to be about 65 m.y. from the ages of the sediments sampled; that is, about anomaly 26. The magnetic profiles are, however, not long enough to compare a synthetic model with the observed profiles and thus to test this age against the Heirtzler time scale. The absence of large anomalies to the north-east of 112 agrees with the suggestion that the positive peak near the site is anomaly 26, in which case the central negative anomaly would be at 64 m.y. The switch of spreading axis therefore probably took place during the period 64 to 60 m.y. ago.

If the western end of the Gibbs Fracture Zone is a transform fault[2], the pre-Palaeocene spreading centre to the south of it must be further east. The eastward end of this transform fault might be found in the south-eastern margin of Rockall Plateau and the anomalies perpendicular to this may be parallel to this spreading centre. A second, parallel fracture zone may be linked to the south end of the Jean Charcot fault[22] in Rockall Trough. The suggestion that the south end of Rockall Trough has resulted from north-east–south-west transform faults bounding north-west–south-east magnetic anomalies is contrary to previous ideas that a spreading axis lay parallel to the trough.

Further evidence for the switch in orientation of the spreading axis comes from the magnetic anomaly pattern immediately south of the east end of the Gibbs Fracture Zone at 51° N, 22° W (Fig. 4). Anomaly 24 runs north–south along 22° W whereas, immediately to the east of this, the anomaly trend is north-west–south-east. This north-west–south-east anomaly is associated with a pronounced basement ridge similar in many ways to that at site 112, which may therefore be a remnant of the pre-Palaeocene spreading centre to the south of the Rockall Trough transform fault. Similar remnants have been reported to the south of the Gibbs Fracture Zone in the western Atlantic by Le Pichon (personal communication).

Reconstruction

A tentative reconstruction (Fig. 7) can be made for anomaly 31 (72 m.y. or Late Cretaceous) using (*a*) the three suggested transform faults, and (*b*) the position of spreading centres of (i) the central Labrador Sea in the same position as after 60 m.y., (ii) the southern Labrador Sea on the ridge near site 112 and (iii) the Atlantic on a median line between anomalies 31 on either side. The continuity of anomaly 31 south of Rockall Plateau[20] suggests that the transform faults between 50° and 53° N did not exist at this time and that the spreading axis was therefore inclined to the 60 m.y. year spreading axis.

It is difficult to take this reconstruction further back in time. But clearly Greenland can be made to fit into Labrador in the position indicated by Bullard *et al.*[23]. With Rockall Plateau attached to Greenland, no problems of overlap would

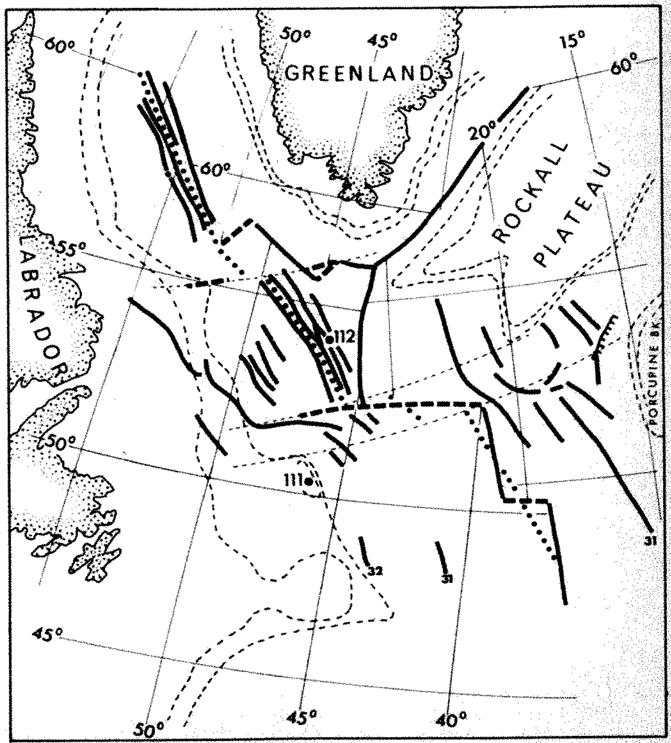

Fig. 6 Palaeogeographic reconstruction at anomaly 24 (60 m.y., Palaeocene). — — —, Possible small circles of transform faults; . . . , spreading axes before 60 m.y. ago.

ensue, but the east–west and north–south scarps at the south-west end of Rockall Plateau would not be explained. The wide separation of anomalies between the two ends of the two transform faults associated with Rockall Trough suggests that they are older than anomaly 32 (76 m.y.) and would imply that the true continental margin off Labrador at 51° N is towards the shelf break. It does not explain the continuation of Rockall Trough to the north-east. South of this, both Porcupine Bank in the east, and Orphan Knoll and Flemish Cap in the west appear to be partially detached pieces of continent which need to be restored to their original position before this region can be reconstructed. Anomaly 32 (76 m.y.) places a minimum age on the separation of Europe from Canada. Linear extrapolation of the spreading rate between anomaly 31 and 32 back to the Labrador shelf edge at 49° N indicates that its age is 82 m.y.

The stratigraphic history of Orphan Knoll (site 111) shows that during the Late Cretaceous (100 to 70 m.y. ago) the sediments deposited there were neritic. By the Maestrichtian (70 m.y.), Orphan Knoll had subsided to about 200 m depth, whereas before 100 m.y. it was probably non-marine. This is consistent with an age of splitting of Europe from Labrador of about 80 m.y. Appreciable subsidence of Orphan Knoll to oceanic depths did not, however, take place until the early or middle Tertiary, by which time a considerable width of North Atlantic Ocean had been formed. The adjustment of the continental margins to an equilibrium state after the initiation of an oceanic split seems to take several tens of millions of years, a time constant that may reflect the creep of lower crust or upper mantle in response to non-isostatic conditions. Alternatively the late subsidence may be the result of later tectonic activity.

This reconstruction follows closely that suggested by Le Pichon *et al.*[2], but differs in suggesting that Rockall Trough did not open as a spreading axis, but as part of an earlier transform fault. A slight revision of Le Pichon's timing gives the sequence of events: (1) 82 m.y.: European plate (with Rockall Plateau and Greenland) breaks from Labrador pulling off fragments of Porcupine Bank, Flemish Cap and Orphan Knoll; (2) 82 m.y. to 60 m.y. (anomaly 24): Labrador Sea and North Atlantic open; (3) 60 m.y. (anomaly 24): Rockall Plateau breaks from Greenland initiating a triple junction and a shift of spreading axes and fracture zones to accommodate the new geometry; (4) 60 m.y. to 47 m.y. (anomalies 24 to 19): simultaneous opening of Labrador Sea, Reykjanes Ridge and North Atlantic; (5) 47 m.y. (anomaly 19): Greenland stops moving relative to Labrador, and Labrador Sea growth finishes; (6) 47 m.y. to present (anomalies 19 to 0): Reykjanes Ridge and North Atlantic grow as European plate separates from Greenland–Labrador plate[15].

JOHN D. ESTES, H. C. TURNER & ROBERT J. HUEBNER
Viral Carcinogenesis Branch, National Cancer Institute, Bethesda, Maryland

The presence of the indigenous latent C-type RNA tumour virus genome can be demonstrated in wild house mice by detection of gs antigen and C-type particles. There seems to be strong suppression of the activity of this viral genome in this feral species.

ALTHOUGH laboratory strains of mice have been subjected to extensive cancer virus investigations, wild house mice (*Mus musculus*) have received limited attention[1-4]. There are no reports of this isolation of murine leukaemia and sarcoma viruses nor of C-type virus particles from wild house mice, but recently our associates have reported the presence of group specific (gs) antigens of the murine C-type viruses in the tissues of wild mice bred in captivity[5]. Since the genome of this species has been demonstrated in all laboratory strains of mice tested[5-7], we set out to look for the murine C-type viral genome in feral wild house mice.

In 1968, we began a study in Los Angeles County (*a*) to detect and determine the natural history of the C-type tumour virus expression in wild mice and (*b*) to study the effect of chemical carcinogens on the expression of the viral genome. Here we report our findings on the prevalence of detectable gs antigen by complement fixation and of C-type particles by electron microscopy in tissues from recently trapped wild mice and from mice kept in captivity for 16–26 months, some of which have recently developed spontaneous tumours, and from young and old mice following tumour induction by 3-methylcholanthrene (MC).

Treatment of Mice

About 600 wild mice were trapped alive in urban Los Angeles, weighed and individually housed in mason jars. Several hundred mice were killed without treatment and 180 were set aside without treatment to live out their life span (geriatric colony). The remainder were equally divided by sex into three treatment groups. One group of 150 mice was inoculated subcutaneously with 300 μg and another group of 50 mice with 150 μg of MC dissolved in 0.05 ml. of trioctanoin. A control group of 146 mice received a 0.05 ml. subcutaneous dose of trioctanoin alone. Sera, collected from all mice by retro-orbital puncture immediately after capture and at the time of tumour collection, were tested for antibodies in complement fixation against eleven murine viral antigens*. Ten per cent sonicated aqueous extracts of (*a*) spleen from the untreated mice, (*b*) spleen from the control trioctanoin injected mice and (*c*) tumour and spleen from mice with induced or spontaneous tumours were tested for complement fixing murine gs antigen by the microtitre technique[8] using, as antiserum, a 1 : 20 dilution of serum pools from Fisher rats bearing transplanted sarcomas induced by the Moloney strain of murine sarcoma virus (MSV)[9].

Sections of tumour and spleen were also prepared for light and electron microscopy. At the time of collection of each MC-induced tumour a trioctanoin injected control mouse was killed and the tissues similarly processed. The time of initial appearance of MC tumours was noted but tumours were allowed to reach 25–35 mm in size before the animal was killed unless they showed evidence of ulceration or necrosis. The average weight of the mice at the time of trapping was 14 g, ranging from 8–19 g.

Methylcholanthrene Indices

No significant differences were observed in tumour incidence or latent period before tumour appearance between the 150 μg and 300 μg MC treatment groups, and so these two groups are combined in Table 1. After intervals of 12–15 months, ninety-eight of 135 (73%) surviving mice which had been inoculated with MC had developed tumours at the inoculation site. The latent period varied from 75–458 days with an average of 143 days. Most of the tumours were fibrosarcomas; several had

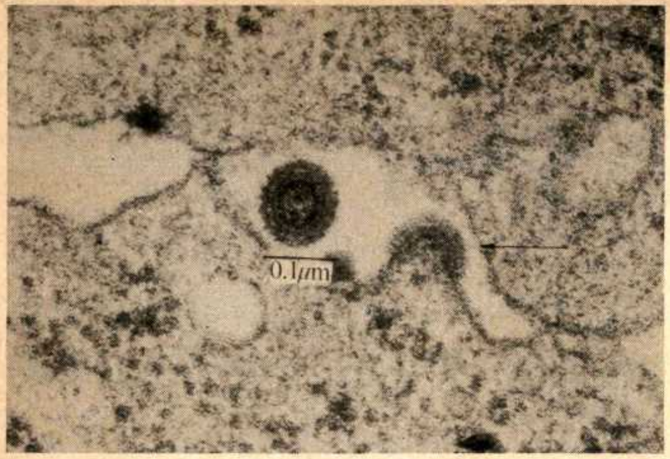

Fig. 1 One budding (arrow) and one extracellular 100-nm C-type virus particle in spleen from a wild house mouse bearing an MC-induced sarcoma. The sarcoma from this mouse also contained C-type particles. (Uranyl acetate; × 105,750.)

features of rhabdomyosarcomas and eleven were squamous cell carcinomas. In two mice both a carcinoma and a sarcoma occurred at the inoculation site. Tumours were not observed by gross or microscopic examination in 146 surviving trioctanoin injected control mice observed up to 18 months.

All inoculated mice remained free of antibodies to the eleven indigenous murine viruses. When we used a highly specific but narrow range MSV rat serum pool (No. 12), selected to contain antibodies reactive only with the species specific major (gs-1) antigen[10], we found antigen in low titre (1 : 2–1 : 4) in six of fifty-eight (10%) tumours tested and in none of the corresponding spleens; but spleen extracts from seven of fifty (14%) recently trapped untreated wild mice also contained gs antigen. In the trioctanoin inoculated control group, two of sixty-one spleen extracts contained gs antigen. Many of these same tissue extracts were thawed after storage for 1 yr and retested with a more broadly reactive MSV rat serum pool (No. 21, see below); positive CF reactions were observed in fourteen of forty-four (32%) MC tumours, ten of forty-four (23%) of the corresponding spleens, none out of twenty-five of the spleens from trioctanoin control mice and thirteen of forty-two (31%) of spleens from untreated control mice (not shown in Table 1).

C-type particles (Fig. 1) were found by electron microscopy in both the MC tumour and corresponding spleen from eight of sixty-six (12%) mice examined. Seven of these tumours were fibrosarcomas, one a squamous cell carcinoma, and all contained detectable gs antigen using the narrow range serum pool (No. 12). C-type particles were not found in any of twenty spleens from the trioctanoin control group. A few were observed in three of twenty-one spleens randomly chosen from the freshly trapped untreated group (see below). Intracisternal A-type particles (Fig. 2) were found in nineteen MC induced tumours, six of which were squamous cell carcinomas and thirteen of which were fibrosarcomas; no C-type particles were detected in these tumours.

In a second experiment (Table 2), twenty old wild mice from the geriatric colony, which had been kept in captivity without treatment for 15 months, were inoculated subcutaneously with 200 μg of MC. Nine of sixteen surviving mice developed sarcomas at the inoculation site after an average latent period of 100 days, when the mice were estimated to be 19–20 months of age. One mouse without a tumour at the inoculation site had a granulosa cell tumour of the ovary.

At this time an MSV rat serum pool of intermediate sensitivity (No. 18) was used for complement fixation tests; this serum pool contained antibodies against the species specific major component (gs-1) and, at lower titres, antibodies against an interspecies cross reacting component (gs-3)[11] of the gs antigen complex. Five of nine (55%) tumour extracts from these old mice contained gs antigen compared with four of thirty-one (13%) MC-induced tumour extracts from young adult mice tested with the same rat serum pool No. 18 (Table 1); several of the tumours from older mice were positive at titres higher (1 : 4–1 : 16) than those observed in younger mice with tumours induced by MC. In the older mice C-type particles were present in two of eight MC-induced sarcomas and in spleens of the same animals. Complement fixation antigen was detected in two of seven spleen extracts and C-type particles were seen in two of eight spleens from normal old mice which had been kept in captivity without treatment for 20 months. All of the old mice also remained free of antibodies to the eleven indigenous viruses described above.

Spontaneous Tumours in Old Wild Mice

Tumours have occurred in sixteen of 150 surviving old mice that had been under observation without treatment for 19–26 months (Table 3). Eight of these tumours were lymphomas, four were fibrosarcomas and four were large pulmonary adenomas. The lymphomas were lymphoblastic and characterized primarily by splenomegaly and generalized lymphadenopathy without thymic involvement. Two of the lymphomas arose in mice subjected 1–2 yr previously to unsuccessful transplants of MC-induced wild mouse sarcomas; the remaining tumours were unquestionably spontaneous. Using more broadly reactive MSV serum pools (Nos. 21 and 25) which contained high titres of antibodies to species specific, interspecies gs antigen[12,13] and possibly additional antigens, complement fixing reactions were detected in high titre (1 : 4 or above) in the spleen and/or tumour in all eight lymphomatous mice, and in lower titre (1 : 2–1 : 4) in two of the fibrosarcomas and in each of the pulmonary adenomas. C-type particles were observed in five

Table 1 Tumour Incidence, Murine C-Type Tumour Virus gs Antigen and C-Type Particle Expression in Young Adult Wild Mice Untreated and after Inoculation with Methylcholanthrene

Treatment	Tumours †	Tissue	CF gs antigen * MSV-12	CF gs antigen * MSV-18	C-type particles	A-type particles
Methylcholanthrene, 150 or 300 μg subcutaneously	98/135 ‡	Tumour	6/58 §	4/31	8/66 ‖	19/66 ¶
		Spleen	0/60	2/31	9/61	5/61
Control—trioctanoin	0/146	Spleen	2/61		0/20	2/20
No treatment—killed immediately	0/121	Spleen	7/50		3/21	1/21

* The MSV rat serum pools utilized differed in sensitivity but not specificity for the murine C-type tumour virus gs antigen. MSV-12 was least sensitive and MSV-18 was of intermediate sensitivity (see text). The mice tested with MSV-18 were different from those tested with MSV-12.

† Number of tumours/number of surviving mice.

‡ Eighty-seven sarcomas and eleven squamous cell carcinomas (including two cases of combined carcinoma and sarcoma); period of observation 12–18 months. Latent period range 75–458 days with an average tumour latent period of 143 days.

§ Number positive/number tested free of anticomplementary activity.

‖ All eight tumours and six of the corresponding spleens were positive for complement fixing antigen; seven of these tumours were fibrosarcoma and one a squamous cell carcinoma.

¶ Six of the nineteen tumours with A-type particles were squamous cell carcinomas; three of the five spleens with A-type particles were from mice with squamous cell carcinomas.

Table 2 Tumour Incidence, Murine C-Type Virus gs Antigen and C-Type Particle Expression in Old Wild Mice Untreated and following Inoculation with Methylcholanthrene

Treatment	Tumours †	Tissue	CF gs antigen * MSV-18	C-type particles	A-type particles
Methylcholanthrene 200 μg subcutaneously	10/16	Tumour	5/9	2/8‡	2/8
		Spleen	3/9	2/10	1/10
Methylcholanthrene 200 μg subcutaneously—non-tumour group	0/6§	Spleen	0/7	1/6	0/6
No treatment—age-matched controls from geriatric colony	0/8‖	Spleen	2/7	2/8¶	2/8

* MSV-18 was of intermediate sensitivity for the complement fixing gs antigen (see text).

† Number of tumours/number of surviving mice.

‡ C-type and A-type particles were in different tumours. The two tumours and one of the two spleens with C-type particles were complement fixing antigen positive.

§ The six surviving MC-inoculated mice without tumours were killed 148 days after inoculation.

‖ These eight mice were killed after 18 months in captivity.

¶ These two spleens had both C-type and A-type particles but were complement fixing antigen negative.

Table 3 Spontaneous Tumours in Wild Mice

Type of tumour †	Tissue	CF gs antigen * MSV 21 and 25	C-type particles	A-type particles
Lymphoma	Lymph node tumour	4/4‡	4/4	0/4
	Spleen	8/8	3/5	1/5
Sarcoma	Tumour	3/4	0/5	1/5
	Spleen	1/5	0/4	1/4
Pulmonary adenoma	Tumour	4/4	0/3	1/3
	Spleen	1/4	0/2	0/2

* MSV-21 and MSV-25 were of greatest sensitivity for the murine C-type tumour virus gs antigen (see text).

† The lymphomas were lymphoblastic, nonthymic and primarily involved the spleen. The fibrosarcomas were located in the thigh, low back, face and liver. The pulmonary adenomas each occupied nearly one entire pulmonary lobe. The period under observation before these tumours occurred was 19–26 months.

‡ Number positive/number tested.

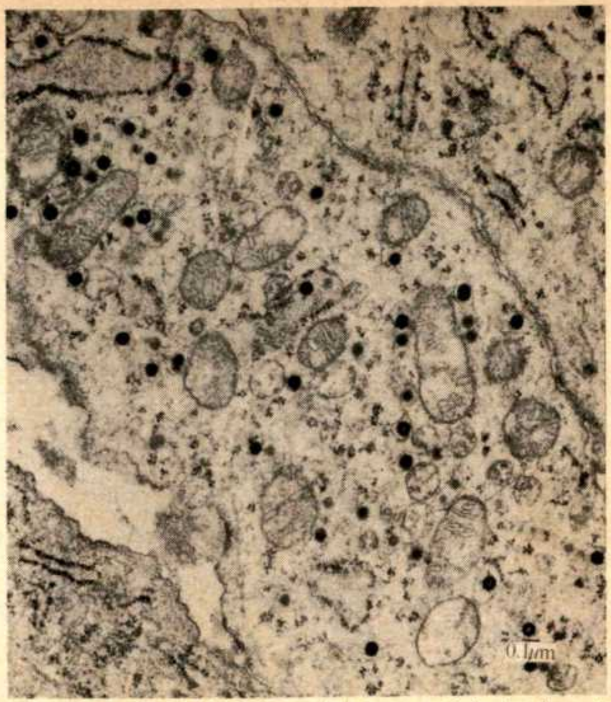

Fig. 2 Many 70-nm intracisternal A-type particles in the cytoplasm of an MC-induced sarcoma cell. (Uranyl acetate; ×22,800.)

of six lymphomatous mice examined but not in the sarcomas or pulmonary adenomas. At the time of tumour harvest, antibodies against polyoma and the other indigenous viral antigens were absent from the sera of the seven mice so tested (lymphoma —4; sarcoma—1; pulmonary adenoma—2). Polyoma virus particles were not seen in any of the MC induced or spontaneous tumours.

Virus Particles and CF Antigen

In a recent preliminary survey of several tissues from freshly trapped untreated wild mice, C-type particles were seen in two of twenty livers, one of six kidneys, six of ten large intestinal mucosae and five of eight uterine endometria. In one embryo a few C-type particles were noted budding from nucleated erythrocytes in the hematopoietic liver. Intracisternal A-type particles were also seen on occasion in this untreated group in postnatal spleen, liver, intestine, skeletal muscle, breast, uterus, placenta and in embryonic liver and skeletal muscle. B-type particles were seen in normal lactating breast tissue from two of four pregnant mice examined. In general, the prevalence of complement fixing antigen in these tissues, using the most broadly reactive MSV rat serum pools (Nos. 21 and 25), was much greater than visualization of C-type particles and those tissues showing C-type particles were usually, although not invariably, positive for this antigen (M. B. G., J. D. E., and R. J. H., unpublished observations).

Implications of the Findings

These findings demonstrate the presence of the C-type RNA tumour virus genome in tissues of feral wild house mice unexposed to laboratory infection or to manipulated breeding programmes. It seems clear that the inbreeding of laboratory mice has produced several strains in which the indigenous RNA tumour virus genome was more frequently expressed in terms of gs antigen, C-type particles and neoplasia than in the natural outbred species[14]; further, several inbred strains have been derived which have segregated for lesser expressions of this genome[14,15]. The percentage of young adult wild mice showing detectable gs antigen in the MC-induced tumours and corresponding spleens and in untreated mouse spleens and other tissues depended on the sensitivity of the MSV rat serum pools used for the complement fixation procedure. With the most narrowly reactive MSV rat serum pool, the gs antigen could be detected in only a small percentage (14%) of spleens from untreated young adult mice or in their MC-induced tumours (10%). This corresponded closely to the prevalence of detectable C-type particles by electron microscopy in the spleens (14%) of untreated young adult wild mice and in the MC induced tumours (12%) and corresponding spleens (15%) of this age group. With the more broadly reactive MSV rat serum pool, capable of detecting a greater proportion of the gs antigenic complex, antigens were detected in larger quantities in MC-induced tumours (32%) and corresponding spleens (23%). The relatively low prevalence of detectable gs antigen in MC-induced tumours using the most sensitive MSV rat serum pool so far available is probably explained, in part, by hypothetical strong cellular repressor mechanisms for RNA tumour virus genome expression in mesenchymal tissues of wild house mice[5]. The comparatively low prevalence of gs antigen detection in spleens and MC-induced tumours (compared with laboratory strains) could also be partly attributed to some degradation of the gs antigen resulting from prolonged storage and repeat thawings of the tumour extracts before retesting with the more sensitive sera. The detection of occasional C-type particles by the electron microscope in both tumour and spleen from only 12% of the mice with tumours also indicates that this latent genome is infrequently activated by MC to form visible virions. Infectious virus, however, has not yet been isolated from any of the MC-induced or spontaneous tumours, including those containing C-type particles, in spite of the use of the most effective virus isolation procedures[7,16,17]*. The findings so far also indicate that in freshly trapped wild mice a few C-type particles may often be seen in various tissues. The extent to which natural activation of this latent murine RNA tumour virus genome to form gs antigen or C-type virions may depend on environmental carcinogens, indigenous DNA viruses such as polyoma, and/or ageing is under study.

In old mice there seems to be less suppression of viral genome activity as suggested (*a*) by the shorter latent period between MC injection and tumour formation, (*b*) by the higher prevalence and titres of gs antigen in tumours and spleens following MC inoculation, and (*c*) by higher incidences of spontaneous tumours in old compared with younger mice and the presence of gs antigen in almost all tumours of the older mice. Whitmire *et al.* also observed that 18 month old BALB/c mice treated with MC developed tumour and gs antigen much more often than younger mice treated with the same dosage of chemical (C. E. Whitmore, R. A. Salemo, L. S. Rabstein, R. J. H., and H. C. T., unpublished).

The absence of demonstrable antibodies to murine RNA tumour virus gs antigen (a 20% clarified extract of a Fisher rat MSV sarcoma) in all mice tested, including those with detectable gs antigen in tumour or spleen extracts, suggests that wild mice, like laboratory mice[18], are immunologically tolerant to this ubiquitous antigen. This was also demonstrated by the absence of such antibodies in wild mice bearing MSV-induced tumours[19]. Such tolerance is perhaps best explained by vertical transmission and embryonic expression of the viral gs antigen which was demonstrated in the tissues of 16–18 day old wild mouse embryos trapped in Maryland[5,19]. The absence of antibodies against polyoma antigen in mice bearing MC-induced and spontaneous tumours suggests that polyoma virus was not responsible for these tumours.

Virus Particles

The significance of the intracisternal A-type particles is unknown. These particles have been seen in several mouse tumours[20], including MC-induced sarcomas[21] and carcinomas[22]. They have also been observed in muscle, liver and other tissues of embryos of a number of laboratory strains (M. L. Vernon, W. Lane, and R. J. H., unpublished observations) and in wild mouse embryos (M. B. G., R. W. R., and J. D. E., unpublished observations). They have not been shown to have biological activity[23], nor do they bear any known developmental or immunologic relationship to C-type particles[21,23]. This point is borne out in the present study where A-type particles were found more often in gs antigen negative normal tissues and tumours while C-type particles were seen mainly in the tumours containing antigen.

The finding of B-type particles in the lactating breast tissue of two of four feral mice examined supports previous experimental evidence that wild mice carry the mammary tumour agent[24]; but this particular RNA tumour virus has not been previously demonstrated in wild mice obtained directly from the feral state. Recent evidence[25] suggests that the B-type virus genome is similar to the C-type virus genome in being vertically inherited and largely repressed in most strains of mice by host cell genetic mechanisms.

It is doubtful that MC tumour induction *per se* could be attributed to superinfection of the tumour by infectious C-type virus particles. Such particles were seldom found in the wild mice treated with MC and, as in laboratory mice, there seems to be no evidence that the virus is communicable in nature. Thus, an MC-induced immunological inability to neutralize infectious C-type virus is probably not an important mechanism in the pathogenesis of MC-induced tumours in wild mice. MC-induced suppression of immune surveillance mechanisms[26], however, may contribute to the proliferative growth of antigenically altered tumour cells. There is much evidence[14,27] to support a role for C-type virus genome activation as a determinant of chemical or spontaneous oncogenesis in laboratory strains of mice. The selective activation of this genome to form gs antigen in the subcutaneous fibrosarcomas induced by MC in laboratory mice but not in adjacent mesenchymal tissue and muscle suggests that activation of this sarcoma oncogene in the tumour cells is often accompanied by activation of the gs antigen of the virogene[5,14,27]. Our study suggests that in wild mice there is a similar causative relationship between chemical and spontaneous oncogenesis, ageing and activation of the latent C-type RNA tumour virus genome.

We thank Rene Germaine for technical assistance. This project was supported by a US National Cancer Institute research contract.

Wobble Excitation by Earthquakes in Real Earth Models

THERE have been several accounts recently[1–4] describing connexions between polar motion and earthquakes. Because a simple correlation is of little significance unless a physical mechanism can be produced to explain it, the most important point discussed in these articles is the question of the efficacy of the mass displacements associated with major earthquakes in exciting the observed polar motion. We wish to report here calculations based on realistic Earth models. The elasticity theory of dislocations[5], used to model earthquake displacement fields, has been generalized to take account of self-gravitation, the radial variation of elastic properties, density and gravity, initial hydrostatic stress and the presence of the liquid core. We have already reported initial results, giving the effect of such realistic Earth model displacement fields on the rotation[6]. Results of a later independent study have been reported by Dahlen[7] and our complete study will be published elsewhere[8].

The calculation of the polar shift and excited Chandler wobble (the free polar motion) is considerably simplified because they depend only on four spheroidal displacement fields of second degree. This obviates the necessity of summing slowly convergent series to obtain the entire displacement field. Fig. 1 shows the radial coefficients of one of the displacement fields affecting polar motion. The six variables shown are the same as those used in free oscillation theory, representing radial displacement, change in normal stress, transverse displacement, transverse shear stress, decrease in gravitational potential and change in radial gravitational flux density, respectively.

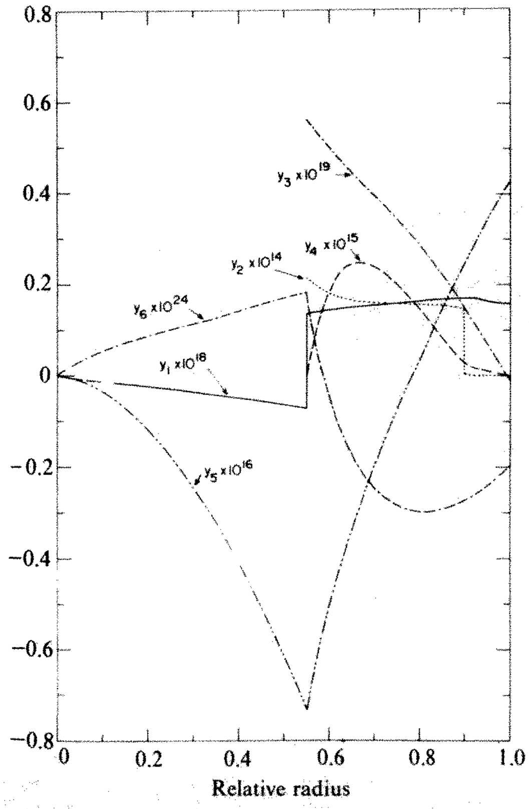

Fig. 1 Radial coefficients of one of the four spheroidal deformational modes affecting polar motion. The units are c.g.s. divided by the slip-fault area product (cm^3). This might be 10^{18} cm^3 for a major earthquake. Focal depth is 0.1 Earth radii.

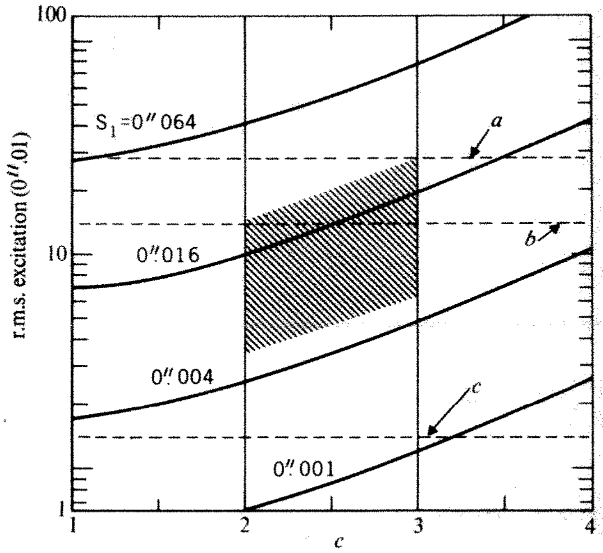

Fig. 2 Root mean square Chandler amplitude in terms of S_1, the average polar shift for an earthquake of Richter magnitude 8.5, and the parameter *c*. The shaded area indicates the degree of uncertainty in the theoretically computed value. *a*, Double observed excitation; *b*, observed excitation; *c*, 1/10 observed excitation.

For the first time in a static problem, the conditions at the core–mantle boundary have been treated without the assumption of the Adams and Williamson relation in the core. This relation takes the density profile to be that for a homogeneous material under compression in an adiabatic temperature field. Jeffreys and Vicente[9] have shown that without the assumption of the Adams and Williamson relation in the core, application of the usual conditions at the core–mantle boundary leads to an insoluble problem. We have shown that in the static case, the conditions at the boundary must be modified; the modification allows the problem to be solved.

We compute that the Chile earthquake of 1960 shifted the pole 1.03 centiseconds of arc towards 269° E, and that the Alaska earthquake of 1964 shifted the pole 1.20 centiseconds of arc toward 51° E. These provide equal and opposite contributions to Chandler wobble excitation. We have used the fault parameters of Plafker and Savage[10] for the Chile earthquake and those of Hastie and Savage[11] for the Alaska earthquake. Both earthquakes were of Richter magnitude $M = 8.5$ but were rather unfavourably oriented for affecting polar motion. For shallow focus earthquakes of Richter magnitude 8.5, the average polar shift is estimated to be between 0.5 and 2.5 centiseconds of arc. The dependence of average polar shift (S_1) on Richter magnitude is given by[12]

$$S_1 \times 10^{(M-8.5)c}$$

where c may have a value from 2.0 to 3.0. The range of the resulting r.m.s. Chandler wobble excitation is shown in Fig. 2.

Ben-Menahem and Israel[2] used a much simpler uniform Earth model and estimated that 30% of the Chandler wobble excitation may be attributed to seismic activity; this is evidently a lower limit. Our theory adequately accounts for the full excitation, but as most geophysical theories tend to be more precise than accurate we must await better measurements of both polar motion and earthquake deformation fields before the argument can finally be decided.

Optical Variability of a Bright New Quasi-stellar Source

BROWNE[1] has identified the radio source 1215+30 of the Bologna B2 survey with a remarkably bright quasi-stellar source of magnitude approximately 14.5. We report here that its optical flux is variable by more than two magnitudes, with discernible brightness changes over time scales of hours, as well as secular trends on a time scale of years.

The light curve of B2 1215+30 (=ON325; J. D. Kraus, private communication) is given in Table 1. The data were obtained by visual estimates from fifty-eight Harvard plates taken between 1926 and 1950 with the f/5 16 inch Metcalf doublet. Table 1 lists (1) the plate number, (2) date, (3) exposure in minutes, (4) object brightness with respect to comparison stars A, B, C and D (identified in Table 2), (5) control brightness estimates of star B with respect to A and C, and (6) of star C with respect to B and D. The sequence A to D is in order of increasing brightness. The relative magnitudes are recorded in standard notation (for example, C9D denotes a magnitude brighter than C by 9/10 of the magnitude interval between C and D). Abbreviations used in Table 1 are bt, brighter than; ft, fainter than; nv, not visible, and s, slightly.

Table 2 gives the coordinates of the comparison stars in centimetres on the finding chart of Browne[1] taking the source as origin, with east to the left and north to the top of the chart. A transfer of magnitudes from nearby selected area 56

Table 2 Position of B2 1215+30

Star	A	B	C	D	QSS
Position (cm)	1.35 E 2.0 S	1.2 W 2.0 N	0.7 E 3.75 N	2.35 W 0.05 N	0.0 0.0

was made on three good quality 120 min exposure RH plates taken with the f/7, 3 inch Ross–Fecker camera. The range of variability was found to be $\Delta m_{pg} = 2.2$ or possibly slightly greater. The absolute range is less certain but is probably between 13.7 ± 0.2 and 15.8 ± 0.2.

Table 1 shows that B2 1215+30 undergoes brightness fluctuations compared with the constant brightness comparisons. The fluctuations occur over months and years, and are even discernible over time scales of hours. For example, the change of 4/10 of the magnitude range B to C in the pairs of plates MC26395, 26397 and MC26443, 26445 is probably real in each case, and occurs over times of 0.10 and 0.14 days respectively. Further inspection of Table 1 shows that the QSS was systematically brighter in 1927/28 than at other times, and systematically fainter from 1929 to 1932, while in 1933 it seems to be systematically somewhat brighter again. The light curve is consistent with the interpretation that the optical output consists of long and short term variability which is known to be characteristic of compact galaxies and quasi-stellar radio sources.

We thank the director and staff of the Harvard College Observatory for hospitality, and the National Science Foundation for support.

Application of Laser Source Mass Spectroscopy to Analysis of Geological Material

The preferred ion source for use in analytical mass spectrography is the spark source in its various forms such as the r.f. spark or the low voltage discharge, but some attention has been devoted in recent years to the possibility of using a focused laser beam to produce ions from the analytical sample[1,2]. The advantage of using such a system lies in its ability to vaporize and ionize non-conducting samples.

Until now, emphasis has generally been placed on the fundamental principles involved, and the use of a laser source has been limited to very specific problems[2]. This communication describes a successful attempt to use a pulsed neodymium laser as a source for the analysis of some elements in geological material.

One reason why lasers have previously been found unpromising as mass spectrographic sources is the slow pulse rates that were available, typically 1 pulse every 30 s. Furthermore severe space-charge broadening effects occurred because often high power Q-switched laser pulses were used, especially in time-of-flight systems.

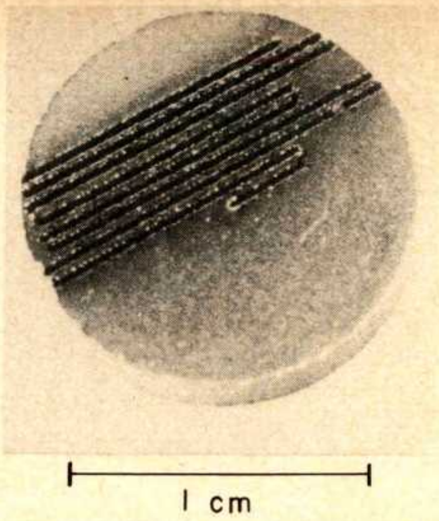

Fig. 2 Sample pellet after laser irradiation.

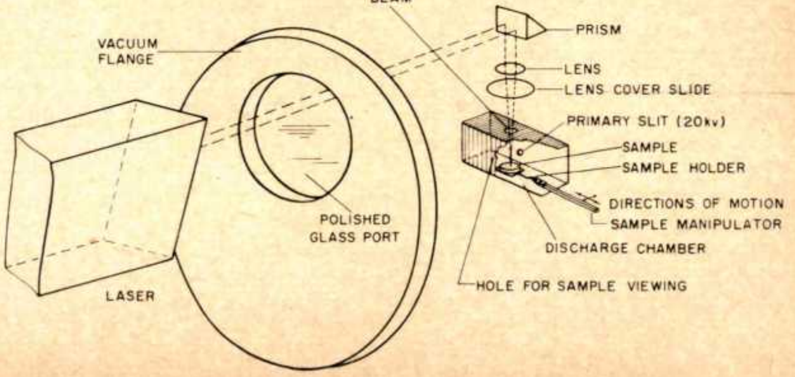
In the study described here, we have used a laser source with a pulse repetition rate of 6.25 s^{-1} in the non-Q-switched mode. Parameters of the laser radiation are given in Table 1. The laser was coupled to a double focusing mass spectrograph (Varian Mat SMIBF) to which some source modifications were made (Fig. 1).

Table 1 Parameters of Laser Radiation

Wavelength	10,600 Å
Mode	Conventional mode
Energy of burst	0.15 J
Total duration of burst	250 μs
Individual spike duration (½ width)	0.1–0.3 μs
Number of spikes per burst	~300
Mean burst power	~0.6 kW
Repetition rate	6.25 s^{-1}

The laser beam was focused on a spot on the sample (in the form of a pressed pellet or a rock chip) in front of the primary slit of the spectrograph. If allowed to, the successive laser pulses would drill into the sample, leading to a rapid diminution in plasma as the vaporization progressed. In the experiments described here, however, the sample was automatically moved laterally in order to present some unvaporized sample surface to each laser pulse. A constant scanning rate of 1 mm min^{-1}, or 3 μm per laser pulse, was found to be satisfactory. A typical sample pellet after irradiation, is shown in Fig. 2.

Fig. 1 Schematic diagram of modified source region of the mass spectrograph.



With the system described the total ion current was of the order 10^{-11} A. An ion-current of this magnitude permits analysis within a reasonably short exposure time. Inspection of the mass spectra revealed an extremely high sensitivity for the alkali metals. Furthermore, the spectral line shape was found to be excellent and much superior to that obtained using spark excitation. Rectilinear line profiles, which have been described as the ideal shape[3], were obtained in all cases using laser excitation. This is presumed to be due to the formation of the plasma envelope at a constant position relative to the primary slit of the mass spectrograph, resulting in an ion beam geometry of constant solid angle.

A problem encountered in pressing pure rock powder such as G1 into a pellet was that the pellet did not bind satisfactorily. To overcome this problem, an admixture of 30% by weight of graphite (to act as binder) was made. We found that the presence of this graphite greatly increased the sensitivity for some elements. Variations in the quantity of graphite showed that in most cases less than 5% by weight of graphite was needed. It is thought that the presence of carbon in the laser plasma creates a reducing environment which assists in the fracture of metal–oxygen bonds.

Table 2 Limits of Detection (p.p.m.) for Typical Elements Found in Rocks*

Element	Without carbon	With carbon
Li	~0.05	~0.05
Na	⩽0.05	~0.05
Mg	100	100
Si	20,000	200
K	⩽0.01	⩽0.01
Ca	20	20
Cr	100	25
Ti	50,000	200
Fe	200	20
Rb	<0.05	<0.1
Sr	50	15
Cs	≤0.1	~0.1

* The following elements were not detected, although present in the sample at greater than 1,000 p.p.m.: carbon, oxygen, fluorine, phosphorus, sulphur, and chlorine. The oxygen was seen as $(M\text{–}O)^+$ complex only.

Assessed limits of detection for some elements in geological samples are given in Table 2. The specificity for the group one elements is noteworthy. We have made use of this characteristic to determine the lithium isotopic ratios in a number of terrestrial and extra-terrestrial samples which have reasonably low lithium levels.

The ^{7}Li/^{6}Li ratio obtained for W1 was 11.1±0.3 in good agreement with the accepted value of 11.15. Values obtained for a number of South African stony meteorites were in the region of 14.0. Further studies of isotopic ratios are being undertaken.

Thus it has been shown that a medium pulse repetition rate laser can be successfully used as a routine source in mass spectrography where good sensitivity for the alkali metals is required. The excellent line shapes that can be obtained and the feasibility of *in situ* analysis of non-conducting samples are important advantages of the system described.

Transformation of Hematite to Goethite in Soils

In many parts of the world, especially in those that were not glaciated during the Pleistocene epoch, red hematitic soils that formed in a previous climate (different from the present one) still exist. In regions where the present climate is cooler and more humid than the previous one, the red colour seems to be disappearing and being replaced by more yellowish-brown colours that indicate the mineralogical transformation of hematite (α-Fe_2O_3) to goethite (α-FeOOH).

Near to the surface of profiles of these soils the proportion of red coloration decreases during these changes and the proportion of yellowish-brown colouring increases. A yellowish-brown rim forms on red mottles (in soils formed in the so-called mottled zones of former laterites exposed by truncation, for example) and this rim gradually grows inwards leaving only a red core that finally disappears. Hard nodules display a thin yellow skin covering a reddish hematitic interior. I have observed these features in areas as different as the North Island of New Zealand, South and Western Australia, Ceylon, Hong Kong and in south-eastern United States[1]. Other people have observed them in Northern Japan[2] and Natal, South Africa[3].

Both the reason for this transformation and its mechanism are closely connected to the change in the organic matter regime of the soil, which in turn reflects climatic change. A cooler and more humid climate causes a slower decomposition rate of the organic matter. In these conditions, increased amounts of organic compounds migrate into the soil and dissolve the hematite by reducing and/or complexing the iron. When this iron is reprecipitated (sometimes following oxidation) the newly formed oxide is usually goethite.

These observations are supported by laboratory experiments with synthetic iron oxides. In the *p*H range of most soils of humid climate areas (3.5 to 7.5) amorphous ferric hydroxide usually crystallizes *in vitro* to a mixture of goethite (through solution) and hematite (probably through internal dehydration). Hematite formation is stopped if the precipitation of the amorphous hydroxide is inhibited, or, in cases where it is formed, if it is prevented from dehydrating to hematite. This can happen when the iron released on weathering is complexed by organic compounds or when such compounds are adsorbed on the hydroxide. Recent experiments in this laboratory have shown that oxidation of ferric citrate yields pure goethite in a *p*H range where goethite and hematite are formed from ageing of amorphous ferric hydroxide[5]. Thus the higher the concentration of the organic compounds compared with the rate of Fe release from primary silicates, the greater the probability that goethite will be the dominating or only ferric oxide formed. The hematite–goethite ratio in soil therefore reflects the carbon regime and, in turn, the climate[4].

The influence of organic matter is further supported by several observations. In cases where roots penetrate into old red soils, removal of iron normally occurs in the vicinity of the roots, forming a bleached zone around them. Some distance out from the root, the iron reprecipitates and forms a yellow rim that separates the bleached zone from the red soil matrix. Furthermore, a red soil which had come into close contact with a humus-rich surface soil by erosion and deposition showed a red→yellow transformation in the area of contact between the two layers. A similar hematite→goethite transformation through solution can also be observed in hydromorphic soils on red hematite sandstone (Bunter Sandstone, for example) in mid-Europe, where, under anaerobic conditions, hematite has gone into solution and the newly formed oxide is always goethite or lepidocrocite, but never hematite.

No change in climate has so far been definitely established at any of the localities where the colour change was observed. But from the striking similarities between the colour of soil profiles in these areas, and those in areas where such a climatic change could be proved and the soils are definitely palaeosols (for example, Australia, N. Japan), a generalization seems to be justified. Therefore observations on these soils may have implications for palaeoclimatology.

Soils in which hematite (as well as goethite) is presently forming are well aerated and permeable, and slightly acid to calcareous. They occur under a warm subhumid to semiarid mediterrane or even arid climate (for example, Red Brown Earths of Australia[6], Hamra soils of Israel, Red Desert Soils of California[7,8]). This is in accord with the idea of a low ratio between supply of organic compounds and Fe release by weathering favouring hematite formation. Perhaps hematite is also forming in soils under moist tropical climatic conditions, where organic matter decomposes rapidly compared with a high rate of Fe release in acid conditions. This is, however, somewhat uncertain as many soils in these areas are probably non-recent and thus may have been influenced during their formation by other climates. Also at least some of the recent soils in these areas are brownish in colour rather than red.

In Support of a Physical Explanation of Ball Lightning

THE purpose of this communication is to present additional evidence in favour of the exclusion of explanations of ball lightning[1-6] in terms of, (*a*) the retinal afterimage hypothesis, (*b*) the intense point discharge hypothesis and (*c*) the burning material hypothesis. Altschuler[7] lists these in his summary of possible explanations.

During a dinner on the evening of July 6, 1971, at Orselina, near Locarno, Switzerland, I observed a flash of lightning which struck an unidentified target near the roof of a building about 200 m away. An intense point discharge immediately followed the flash and was visible clearly at the target for 1 or 2 s. I immediately told the other people at the dinner (Professor E. H. Schröter and Dr E. Wiehr from Göttingen and Mr C. Kühne from Oberkochen) of my observation because they were not looking out of the window at the time.

This occurrence was unmistakably different from another lightning event, which I observed several years ago and which I consider to have been a rare event of actual ball lightning. At that time a thunderstorm accompanied by heavy rain took place in the area of Neustadt near Coburg, Germany. I was sitting with some other people (among them Mr C. Förster from Berlin) right behind a ground floor window so that I could look at the weather; the field of view out to the street was limited by the frame of the window. Suddenly, at a height of about 16 m above the ground and at a short range of about 24 m, I saw a spherical plasma ball coloured bright yellow-white. This object appeared to have a diameter of 50 to 100 cm. It moved vertically downwards with a speed of about 4 m s^{-1}, and its path ended in the top branches of a tree, at a height of approximately 9 m. On touching the tree the ball instantly disintegrated into eight to twelve smaller spheres. These were the same colour as the large one and each had a diameter to 12 to 15 cm. They fell to the ground, guided by the outer contour of the tree, and moved vertically during the last few metres in the absence of branches. On reaching the ground (an asphalt roadway and a neighbouring footpath) the spheres instantly disappeared. There was no noise apart from that of the rain and no lightning associated with the primary plasma-like sphere. Three to five minutes afterwards, the same phenomenon occurred again in precisely the same way as before, indicating that the conditions needed to produce and guide the primary sphere were still maintained or re-established during the time that had elapsed. Immediately after the rain had stopped, I went out into the street to look for further evidence. There were circular patches of melted asphalt on the wet asphalt cover of the roadway which showed the interference colours of thin layers. Their diameters were each 12 to 15 cm and they obviously marked the impact areas of the smaller spheres. This event was described similarly by all the witnesses.

Because roadway asphalt in general contains B-80 bitumen—a thermoplast from which liquid components disintegrate at about 170° C—one may very roughly calculate the minimum amount of energy needed to produce the observed patches. Assuming that a water layer of thickness 0.5 mm at 20° C was evaporated and that an asphalt layer of thickness 1 mm was then heated to 170° C, and assuming a mean density of 1.0 g cm^{-3} and a mean specific heat $c_p = 0.46$ calorie g^{-1} for B-80, one may easily calculate the energy density of the plasma spheres to be at least 1.9×10^7 J m^{-3}.

Proposal for a New High Precision Particle Detector

THE precision commonly quoted when measuring the position of a charged particle track is ±0.3 mm for wire plane spark chambers[1], ±0.4 mm for streamer chambers[2] and ±0.7 mm for multiwire proportional chambers[3,4]. With the onset of the new generation of synchrotrons there is a need for detectors with better resolution. This arises from the fact that the accelerated particles will receive only small deflexions in analys-

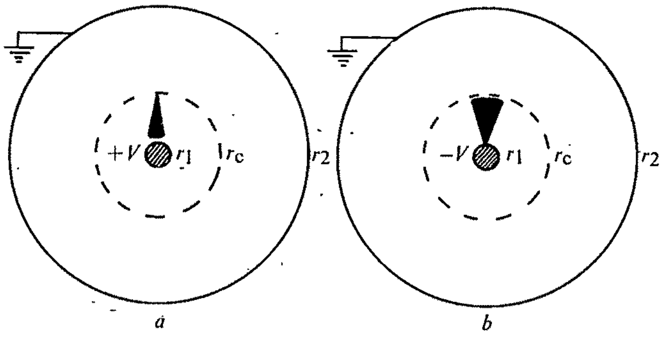

Fig. 1 *a*, Conventional proportional counter; *b*, outwardly directed avalanche chamber. Not to scale.

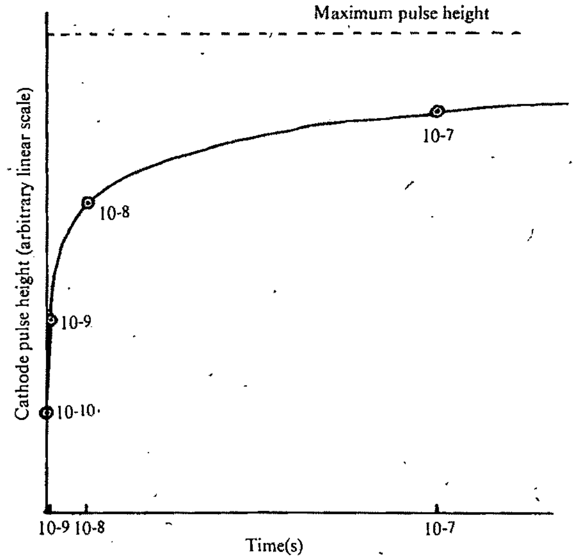

Fig. 2 Pulse formation in the outwardly directed avalanche chamber, calculated for the values mentioned in the text. The ions are collected at the wire cathode at $t_1=4.10^{-9}$ s and the maximum pulse height is obtained at about $t_2=10^{-6}$ s when the electrons arrive at the cylindrical anode.

ing magnets. This article consists of a proposal for a detector that will provide the necessary increase in resolution.

The basic design of the proportional counter has remained unchanged since Rutherford and Geiger[5]. The pulse formation in such a counter has been discussed in detail by Wilkinson[6]. In a radial field where the electric field (E) is related to the applied potential (V) by

$$E = \frac{V}{r \ln r_2/r_1} \tag{1}$$

the electrons, from ion-pairs released by traversing charged particles, drift towards the anode wire (Fig. 1). On arrival at a critical radius

$$r_c = \frac{r_1 V}{V_c} \tag{2}$$

where V_c is the threshold voltage for ionization, secondary ionization starts. An avalanche results, the number of electrons roughly doubling in every mean ionizing path. Of the electrons falling on the wire, half are produced within only one mean path of the wire, and are collected practically instantaneously. The rise-time of the pulse, however, is governed by the drift of the positive ions away from the wire.

I shall consider the opposite design—in which the wire is the cathode. Any free electron at the surface of the wire will be accelerated radially and an outgoing avalanche will be formed (Fig. 1). The multiplication will continue until the critical radius is attained, after which the electrons will drift slowly to the cylindrical anode. The positive ions will accelerate towards the cathode where, on arrival, one assumes that they are merely neutralized. On completion of the avalanche at time $t=0$, one may assert that a shell of positive ions and electrons lies at the critical radius r_c. If the drift velocities be given by

$$\begin{aligned} u_+ &= \frac{dr_+}{dt} = -k_+E \\ u_- &= \frac{dr_-}{dt} = k_-E \end{aligned} \tag{3}$$

where k_+, k_- are the appropriate mobilities, one may show, using Green's theorem, that the growth of the cathode pulse with time is described by

$$P(t) = \frac{Ne}{C \ln r_2/r_1} \ln \left\{ \sqrt{\frac{2k_- Vt + r_c^2 \ln r_2/r_1}{-2k_+ Vt + r_c^2 \ln r_2/r_1}} \right\} \tag{4}$$

where C is the chamber capacity and Ne the charge in the avalanche. The positive ions will all be collected at time

$$t_1 = \frac{(r_c^2 - r_1^2) \ln r_2/r_1}{2k_+ V} \tag{5}$$

and the electrons at

$$t_2 = \frac{(r_2^2 - r_c^2) \ln r_2/r_1}{2k_- V} \tag{6}$$

Let the radius of the wire be 20 µm and that of the cylinder 1 cm. Suppose that the threshold voltage (V_c) is 1,200 V and the operating voltage 2,000 V. Then from equation (2), r_c is 33 µm. The avalanches will thus have a radial distance of 13 µm in which to develop. If the counter is filled with argon at atmospheric pressure, taking[6] $k_+=2.5$ cm^2 V^{-1} s^{-1} and $k_-=2{,}000$ cm^2 V^{-1} s^{-1}, the pulse in Fig. 2 is obtained. Thus 22% of the maximum pulse is attained in 10^{-10} s and 65% in 10^{-8} s. The sharp rise means that a short detectable fast pulse may be obtained with a differentiation network.

If the "outwardly directed avalanche chamber" is to be a viable detector, particles must produce one free electron near the wire surface. The primary specific ionization in argon is about 27 ions/cm. Assuming that an electron produced inside a radius of 26.5 µm will result in a detectable pulse, the available distance is 13 µm—counting both sides of the wire. The chance of an ion-pair being produced in this distance is therefore $(13.10^{-4})(27)=3.5\%$.

When a particle passes through the wire, a secondary electron may be emitted from the surface. This probability, δ, is thought to be independent of energy at high energies. Per-

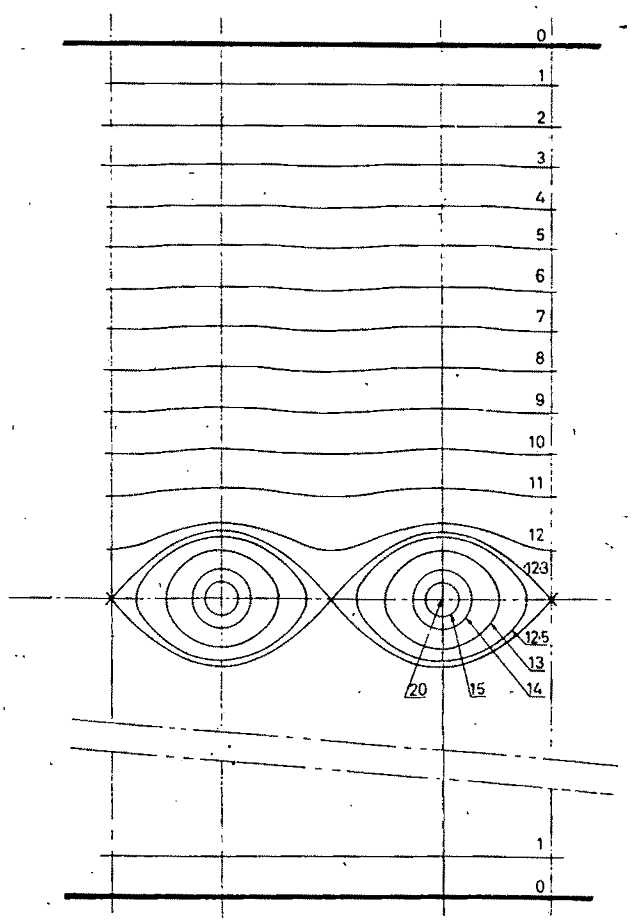

Fig. 3 The equipotentials surrounding the wires of a cathode wire-plane when placed between two plane anodes. It has been possible to take the figure from Charpak *et al.*[3,4] as the electric field will have the same shape whether the wires be cathodes or anodes.

tinent values for δ are difficult to find. A value of $\delta = 2.5\%$, however, has been given for 19.2 GeV/c protons traversing 5 µm aluminium foils[7]. Applying this to entrance and exit surfaces, the probability then becomes 5%. Bruining[8] has mentioned that for 80 kV electrons, the probability increases by a factor 2 when the aluminium thickness increases from 3.6 to 9.4 µm. It seems reasonable therefore to use a factor 2 in applying the 5 µm value to 40 µm wire. Bruining has also commented on the effect of the density of the wire. For 300 kV electrons, the emission from tungsten (density 19.3 g cm^{-3}) was 3.6 times that from aluminium (2.7 g cm^{-3}). Thus if we use stainless steel wires coated with gold (density 19.3 g cm^{-3}) our probability figure would become 36%—and more if the high field of the wire geometry enhances electron emission. Of course, these are rough estimates.

Quenching gas would be required to neutralize spurious ions produced by cosmic rays and non-intersecting particles. External quenching might also be necessary to cope with the action of the avalanche ions. Another possibility is to operate in a pure organic quencher—say, isobutane. Nevertheless, electron emission from the cathode might prove to be a difficult problem.

If successfully developed, the outwardly directed avalanche chamber might be used to assess the spatial distribution of particles in a beam. Alternatively, the wires might be arranged in a Charpak[3,4] multiwire format in which the wires avalanche independently (Fig. 3). It is clear that the high resolution (~30 µm) is bought at a cost of low efficiency—for example, a plane of 30 µm wires, spaced at 1 mm would be 97% transparent. Optimistically, one can envisage matrices comprised of hundreds of planes each with hundreds of wires.

I thank Drs Andreas Weitsch, Branko Bošnjaković, Robert Klanner and C. Schmied for discussing this work; and Professor P. Preiswerk and Dr Werner Kienzle for their hospitality at CERN, and also the Science Research Council for making my visit to CERN possible.

BIOLOGICAL SCIENCES

Prostaglandin-induced Myometrial Activity inhibited by Progesterone

PROSTAGLANDINS (PGs) are being used increasingly as abortifacients although their precise mechanism of action is uncertain. One of the compounds frequently used is PGF$_{2\alpha}$, which has been shown to stimulate the myometrium *in vitro*[1] and *in vivo*[2]. Whether or not the direct action of this agent on the uterine muscle alone is responsible for the interruption of pregnancy is not clear, but the long interval between infusion and abortion[3] suggests that other mechanisms might be involved; for example, a luteolytic effect[4–6]. The prompt increase in uterine activity after treatment with prostaglandin, however, argues that the direct effect plays some part in the abortifacient action. Little is known of the influence of other myometrial regulatory agents such as the ovarian steroids on the uterine response to PGs. Accordingly we examined the influence of progesterone on myometrial responses to prostaglandin F$_{2\alpha}$ in the rabbit, a species in which progesterone is known to have a blocking action on the uterine muscle[7].

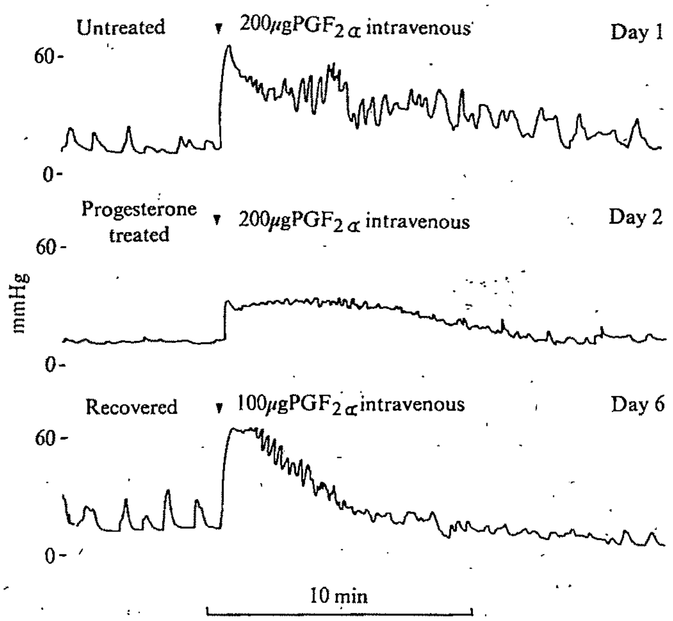

Fig. 1 Intra-uterine pressure recordings from a non-pregnant rabbit showing the response to an intravenous injection of prostaglandin PGF$_{2\alpha}$ before treatment with progesterone (day 1) during the progesterone effect (day 2) and after recovery from progesterone (day 6). NB. Treatment on day 6 was only 100 µg of PGF$_{2\alpha}$ whereas, on days 1 and 2, 200 µg of PGF$_{2\alpha}$ was used.

Adult non-pregnant New Zealand White rabbits were equipped with intra-uterine recording balloons as described by Csapo, Takeda and Wood[8] and intra-uterine pressure monitored via Statham pressure transducers and a Grass 7B polygraph. In twenty-three tests with four rabbits PGF$_{2\alpha}$ was administered by single intravenous injections of either 100 or 200 µg before, 12–14 h after treatment with 10 mg progesterone given subcutaneously when the inhibitory effect of this hormone on spontaneous myometrial pressure cycles was maximal, and also following recovery from the progesterone effect. In all animals the uterine response to both doses of PGF$_{2\alpha}$ was one of an immediate contracture. But, in the progesterone treated animals the amplitude, and with the 200 µg dose the duration, of the contracture was significantly less than in the untreated animals (Table 1). Following prostaglandin treatment rhythmic pressure cycles recurred before the resting pressure returned to the pre-treatment level in intact and recovered animals, but were reduced to a mere ripple (Fig. 1) in the progesterone treated rabbit. Injection of 200 µg of oleic acid intravenously as a control elicited no response from the uterus. In two further animals the effect of progesterone on the uterine response to the intravenous infusion of PGF$_{2\alpha}$ was examined. Whereas a single injection of 100–200 µg PGF$_{2\alpha}$ elicited a marked contracture of high amplitude, infusion of a similar quantity of the substance over a period of 30 min produced no elevation of the resting pressure but increased the frequency of pressure cycles by more than 100% (that is, mean frequency before treatment was 45.6 ± 13.0 s.e. pressure cycles/h, during infusion 94.8 ± 18.4 s.e./h (before against during $P < 0.1$) and after infusion 27.6 ± 7.0 s.e./h (during against after $P < 0.01$.) After

Table 1 Myometrial Response to $PGF_{2\alpha}$ in Untreated, Progesterone-treated and Progesterone-recovered Rabbits (Four Animals)

	Treatment intravenous	Untreated and recovered ±s.e.	Progesterone treated ±s.e.	P
Amplitude of response (mm Hg)	100 μg $PGF_{2\alpha}$	37.8±2.2 (8)	22.4±2.2 (3)	<0.01
	200 μg $PGF_{2\alpha}$	40.8±3.7 (6)	24.8±3.3 (6)	<0.001
P		>0.1	>0.1	
Duration of response (min)	100 μg $PGF_{2\alpha}$	9.5±0.9 (8)	9.7±0.6 (3)	>0.1

treatment of the animals with 10 mg progesterone, this response was either totally abolished or so reduced as to be almost imperceptible, but returned on recovery from the progesterone block.

These results demonstrate that progesterone inhibits the myometrial response to $PGF_{2\alpha}$ in the rabbit. This might be due to its action in impairing the electro-coupling of cells[7], or in reducing their reactivity by hyperpolarization of their cell membranes[7], or both. Whatever the underlying cause it is clear that $PGF_{2\alpha}$ is a much less effective oxytocic agent in the presence of the progesterone-block. The significance of this in relation to its abortifacient action in women cannot be judged until the role of progesterone itself in maintaining human pregnancy is clarified. If progesterone is a major uterine regulatory agent in the human female, then the results of these experiments suggest that alternatives to a direct action on uterine muscle such as an interference with steroidogenesis should not be overlooked in seeking the mechanism by which prostaglandins induce abortion.

We thank Miss Marilyn Murray for technical assistance, Drs G. W. Duncan and J. E. Pike for prostaglandin and the Milton Fund of Harvard Medical School for financial support.

Necessity for Restudying Nucleic Acid and Protein Synthesis in Mammalian Semen

IT is generally accepted that mature spermatozoa cannot synthesize nucleic acids[1]. The only enzyme involved in nucleic acid synthesis which has been identified in semen is polynucleotide phosphorylase[2], but this finding remains unconfirmed, and it has been suggested that the apparent enzyme activity resulted from interactions of other enzymes not involved in nucleic acid synthesis[3].

We have reported the existence of a very potent compound in bull seminal plasma and sperm cell extracts which inhibited tRNA methylation[4,5] by degrading the tRNA substrate into non-dialysable polynucleotide fragments[6]. Evidence strongly suggested that the active compound was not a ribonuclease, but a polysaccharide which formed an irreversible complex with the tRNA before degradation of the tRNA[6]. Data are presented here to demonstrate that very dilute amounts of seminal plasma or sperm cells are sufficient to hydrolyse all species of RNA. Consequently, the activity of exogenously added enzymes which synthesize RNA, or utilize it as a substrate or template, were undetectable in the presence of either of the semen components.

Semen from stud bulls collected over liquid nitrogen was supplied by the Eastern Artificial Insemination Corporation, Ithaca, New York. No antibiotics or preservatives were added to the final pooled sample. R17 viral RNA was provided by Dr James Eley. Ribosomal and transfer RNA samples were purchased from Miles Laboratories and General Biochemical Company, respectively. Bovine pancreatic ribonuclease and all nucleotides were purchased from the Sigma Chemical Company.

Seminal plasma was separated from sperm cells by centrifugation at 850*g* for 10 min. The sperm cells were washed twice with 0.25 M sucrose before use. Trichloroacetic acid was added slowly to 1 : 80 diluted samples of the semen components until solutions were made 7% with respect to the acid. After centrifugation, the supernatants were neutralized with NaOH and dialysed against water for 24 h before use. Final dilutions were made with distilled water. Preparing semen extracts in this manner inactivated an endogenous ribonuclease which preferentially hydrolyses double-stranded RNA (ref. 7 and B. S. and S. M. W., unpublished).

Percentage hydrolysis of the RNA samples was determined by incubating 0.1 mg of each species of RNA with various dilutions of seminal plasma or sperm cells in 1.5 ml. of 0.02 M Tris buffer (*p*H 7.8). After 30 min at 37° C, 0.2 ml. of 50% trichloroacetic acid was added to the assay mixtures to terminate the reactions. The mixtures were then kept at 4° C for 15 min before being centrifuged. The 260 nm absorbtion of the supernatant solutions were then read to determine the amount of acid soluble products. Concurrent blanks were assayed with each individual concentration of seminal plasma and sperm cells.

Tables 1 and 2 show the percentage hydrolysis of the different species of RNA after being incubated with various dilutions of the semen components. Dilutions as low as 1 : 2,500 of seminal plasma, and 1 : 500 of sperm cells, were

both able to hydrolyse totally 0.1 mg of tRNA, rRNA, polyuridylate or R17 viral RNA. There were no significant differences in the percentage hydrolysis of tRNA samples isolated from different sources.

Because of the degradation of RNA, these dilutions of the semen components completely masked the activity of exogenous enzymes which required RNA as a substrate, such as tRNA methylases[5], rRNA methylases[5] and valine tRNA aminoacylase[8]; and enzymes which synthesize RNA such as DNA-dependent RNA polymerase[9], and uridine diphosphate polymerase[10]. These data were independent of the degree of activity of the exogenous enzyme preparation. Where applicable, 0.1 mg of RNA was employed as the substrate. Similar results depicting the masking of enzyme activity were obtained with concentrated or diluted samples of seminal plasma or sperm cells which were not treated with the trichloroacetic acid.

Bovine pancreatic ribonuclease activity was not affected by either of the semen components. This may be explained by the fact that the active compound in semen degrades tRNA into non-dialysable fragments[5]. It can therefore be assumed that these fragments, being non-dialysable, are large enough to serve as a substrate for the exogenous ribonuclease. The data in these studies indicate that unless the hydrolytic substance in semen is differentially inactivated, it will be impossible to detect (except for diesterases) any exogenous or endogenous enzyme activity in semen, whereby RNA is synthesized, or utilized as a substrate or template. Initial studies have demonstrated that periodate oxidation destroys the hydrolytic substance in very dilute semen without affecting endogenous nucleic acid polymerase activity. Experiments are now being conducted to determine the proper conditions to inactivate this compound in undiluted semen by periodate oxidation. When this is accomplished, it will be possible to determine whether mature spermatozoa possess the enzyme complement necessary to synthesize nucleic acids and proteins.

Possible Role for Prostaglandin F$_{2\alpha}$ in Parturition in Sheep

PROSTAGLANDINS F$_{2\alpha}$ (PGF$_{2\alpha}$), E$_1$ (PGE$_1$) and E$_2$ (PGE$_2$) have potent oxytocic properties that have led to their successful use in induction of labour and abortion in women[1]. They have been found in tissues and biological fluids of women in spontaneous labour but it is not clear whether the release of prostaglandins has an important physiological role in the control of labour or whether it is a consequence of labour. Karim and Devlin[2] found PGE$_1$, PGE$_2$, PGF$_{1\alpha}$ and PGF$_{2\alpha}$ in amniotic fluid of women in labour although only PGE$_1$ was present in samples obtained before labour. The source of prostaglandins in amniotic fluid may be the decidua, which shows the same pattern of prostaglandins as amniotic fluid—PGE$_1$ before labour and PGE$_1$, PGE$_2$, PGF$_{1\alpha}$ and PGF$_{2\alpha}$ during labour[2]. The decidua may also be the source of PGF$_{2\alpha}$ found in peripheral venous blood[3].

In sheep, the mechanism of onset of labour seems to be controlled chiefly by corticosteroids secreted by the adrenals of the foetal lamb[4]. The length of pregnancy can be manipulated in this species by experimental procedures such as foetal hypophysectomy or foetal infusions of either adrenocorticotrophic hormone or corticosteroids that depress or augment foetal adrenal function. We have investigated the role of PGF$_{2\alpha}$ in premature parturition induced by infusion of a glucocorticoid into the foetal lamb.

Samples of maternal cotyledons, foetal cotyledons and myometrium were obtained by killing ewes with an overdose of phenobarbitone and gallamine and then rapidly excising the tissues. The control ewes were normal pregnant animals of known gestation length. In one experimental group, the foetuses had received an intra-carotid infusion of dexamethasone (1 mg/24 h) either for 24 h or until labour contractions were observed on continuous intra-amniotic pressure recordings (at 46–52 h). In another experimental group the foetuses were infused with dexamethasone for 52–57 h but the onset of labour was prevented by giving the ewe progesterone in oil 100 mg/12 h. Before and during corticosteroid-induced labour large samples of plasma (100 ml.) were obtained by plasmaphoresis from chronically implanted catheters in the maternal jugular (JV) and uterine veins (UV). The fresh samples were immediately frozen on dry ice and stored at −10° until analysed.

Weighed portions of tissue were homogenized in 4 volumes of ethanol at 4° C. The supernatant of the homogenates and the plasma samples were extracted with ethyl acetate at *p*H 3.0 after the addition of 200 nCi of tritiated PGF$_{2\alpha}$. After methylation, the PGE and PGF compounds were separated by thin layer chromatography (TLC) using system M1 of Gréen and Samuelsson[5]. Authentic standards of methylated PGF$_{2\alpha}$ and PGE$_1$ were run beside the unknowns and were identified by spraying with 1% of iodine in methanol. R_F values (relative to the solvent front) of the methyl derivatives of PGF, PGE and PGA were respectively 0.42, 0.605 and 0.87. Areas of the TLC plates corresponding to the standards were removed and the extracts were further identified and purified by paper chromatography at room temperature using a mobile phase of ethylene dichloride/heptane 1 : 1 and a stationary phase of 70% glacial acetic acid. The area

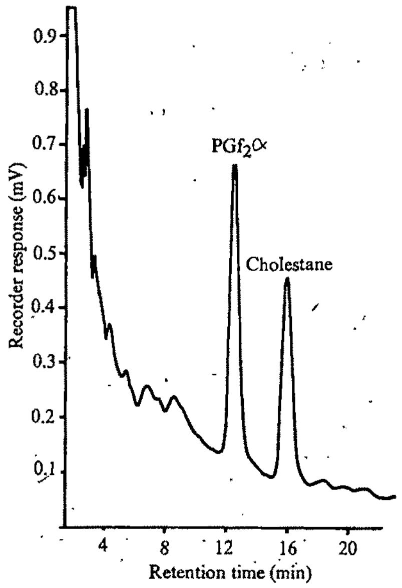

Fig. 1 Gas chromatographic assay of $PGF_{2\alpha}$ in 39 g of maternal cotyledons from sheep No. 0/102. Overall recovery during purification was 36%. One-twentieth of the trimethylsilyl ether derivative of the final extract was injected. Cholestane was added as an internal standard. The $PGF_{2\alpha}$ peak corresponds to 190 ng of authentic material. Column conditions: 1.8 m × 4 mm glass column, 2.03% SE 30 on 80–100 mesh 'Diaport S'. The column temperature was 225° C; injection port temperature was 260° C. Nitrogen flow rate was 25 ml./min.

corresponding to $PGF_{2\alpha}$ was identified by radiochromatogram scanning. The R_F values of PGF, PGE and PGB methyl ethers were respectively 0.52, 0.64 and 0.73. The trimethylsilyl ether derivatives were quantitated by gas chromatography (GLC) using conditions described in Fig. 1 and were also applied to a column packed with 3.8% 'Hi-Eff 3A' on 80–100 mesh 'Diaport S' at a column temperature of 218° C. Cholestane was used as an internal standard for PGF assays. Retention times relative to cholestane for authentic $PGF_{1\alpha}$ and $PGF_{2\alpha}$ were respectively 0.78 and 0.84 on the SE 30 column and 0.45 and 0.45 on the succinate column. PGE compounds eluted from TLC plates were converted to PGB compounds by treatment with NaOH and were then subjected to paper chromatography, acetylation and GLC. The internal standard used for GLC of PGB compounds was 20β-acetoxyprogesterone and the relative retention time of authentic PGB_1 and PGB_2 on an SE 30 column was 0.72. Peaks with the same relative retention time as authentic materials on both SE 30 and succinate columns were measured and the amounts of prostaglandin in the samples were determined from a standard curve. The lower limits of detection of both PGF and PGE compounds were 100 ng/20 g tissue sample and 200 ng/100 ml. plasma sample. Procedural losses were estimated from the recovery of radioactivity after silylation.

$PGF_{1\alpha}$, PGE_1 and PGE_2 were not detected in any of the tissue or plasma samples. $PGF_{2\alpha}$ was not found in any of the JV samples or in UV samples taken before labour but was present in UV plasma during labour in nine of ten ewes (Table 1).

The concentration of $PGF_{2\alpha}$ in maternal cotyledons was raised above the levels found in two control animals after dexamethasone had been infused into the foetus for 24 h, but the concentration in myometrium was unchanged (Table 2). In labour, a further increase in concentration in maternal cotyledons was found and, in addition, the concentration in the myometrium was increased. Similarly increased concentrations of $PGF_{2\alpha}$ were also found in maternal cotyledons and myometrium of ewes that would have been in labour had they not received progesterone. The concentration of $PGF_{2\alpha}$ in foetal cotyledons was relatively low in all samples.

The results show that an increase in concentration of $PGF_{2\alpha}$ in maternal cotyledons precedes the onset of induced, premature labour by at least 24 h. Furthermore, an increase in concentration in both maternal cotyledons and in myometrium occurs not only in labour but also when uterine activity is suppressed by large doses of progesterone, indicating that the appearance of $PGF_{2\alpha}$ is not a consequence of labour. These observations are consistent with a causal relationship between $PGF_{2\alpha}$ and the onset of labour in sheep.

Table 1 Concentration of $PGF_{2\alpha}$ in Uterine Venous Blood before and during Premature Labour induced by Infusion of Dexamethasone into Foetal Lambs

Sheep No.	Length of gestation (days)	$PGF_{2\alpha}$ concentration (ng/m.l) Before labour	In labour
0/6	110	—*	31

0/103	134	275	306	

* Sample lost during purification.

The plasma concentration of progesterone decreases sharply before parturition at term[6] and also before premature parturition induced by administration of corticosteroids or ACTH to the foetus[4]. Although it is likely that withdrawal of the inhibitory effects or progesterone on uterine contractility plays a part in the physiological mechanisms regulating labour in sheep, there is doubt that it is the major mechanism since relatively large doses of progesterone fail to prevent labour[4,7]. Progesterone withdrawal may have a facilitatory role in parturition, secondary to a mechanism that is dependent on prostaglandin release. The recent demonstration that the uterine luteolytic agent is likely to be $PGF_{2\alpha}$ (refs. 8, 9) raises the possibility that $PGF_{2\alpha}$ could serve a dual role in relation to parturition, being luteolytic in species in which luteolysis immediately precedes parturition and being oxytocic in species in which pregnancy is maintained by placental hormones.

We thank the trustees of the Wellcome Trust for financial support, and Dr J. E. Pike, of Upjohn, Kalamazoo, for prostaglandins.

Purity of Synthetic Peptide Preparations

WE strongly endorse Vane's comments[1] on the pitfalls associated with the use of synthetic peptides in biological studies. It is particularly misleading to express results in terms of weight without evidence of homogeneity, because apart from error peptides (which may not be inert), account is seldom taken of salt and solvent content.

The impact of these problems in the field of radioimmunoassay was discussed at some length[2,3] at the recent workshop meeting in Edinburgh. In the case of one commercial synthetic angiotensin already widely used in research, evidence has been recorded of varying stability between batches[4] and apparent variations in the peptide content of different batches[5]. Furthermore, extending Vane's comments on the chemical purity of these peptides, it may not be generally appreciated that rearrangement of the aspartyl residue in angiotensin can occur in solution even at neutral *p*H; the biological activity of the β aspartyl isomer in the rat pressor assay is some 150% that of the α form[6]. The activity of successive batches of peptide could thus differ according to the degree of contamination by the β isomer. If, however, as suggested[1], manufacturers provided comprehensive analytical data for each batch of synthetic peptide, the user would be aware of this possibility.

When precise quantification is needed, the practice of describing results in terms of apparent peptide content is misleading and could be avoided by assay in terms of a suitably characterized standard preparation. Such a preparation of angiotensin II (asp^1 ileu^5 angiotensin II) has been chemically characterized and its stability studied; this preparation (coded 70/302) and also a human renin preparation (coded 68/356) are now available from this division to research workers for the purpose of standardization.

In due course a preparation of human type angiotensin I[7] will also be provided. It is hoped that use of these will make possible valid quantitative comparison of results in the renin/angiotensin field.

We would emphasize that these general comments apply to many of the synthetic peptide hormones used quantitatively in research which include oxytocin, vasopressins, angiotensins I and II, bradykinin, corticotrophins, human calcitonin M and secretin.

Role of Reduced TPN in the Response to Interstitial Cell Stimulating Hormone

DISCUSSING the mechanism of action of interstitial cell stimulating hormone (ICSH), also called luteinizing hormone, on the ovary, Flint and Denton[1] concluded that the "primary steroidogenic response" of rat lutein tissue to ICSH involves no change in the cytoplasmic concentration of TPNH (NADPH). This argument was based on two observations: (i) glucose added *in vitro* to luteal tissue increased TPNH/TPN$^+$ but not steroid synthesis and (ii) ICSH *in vivo* increased steroid synthesis but not TPNH/TPN$^+$. Steroid synthesis was observed to increase by 0.19 μmol/g/h after injection of ICSH. The interpretation proposed reveals a fundamental misunderstanding of the significance of steady state values of TPNH/TPN$^+$ which this letter attempts to clarify.

In steady state conditions the concentration of luteal TPNH (or the ratio TPNH/TPN$^+$) at any one time is the outcome of a balance between production and destruction of TPNH (effectively between the relative rates of oxidation and reduction of the pyridine nucleotide). Clearly, constancy of steady state value of TPNH (or TPNH/TPN$^+$) does not necessarily mean that the rate of reduction of TPN$^+$ remains constant; the only valid conclusion is that the balance between oxidation and reduction has not changed. If the rate of reduction of TPN$^+$ increased two-fold, steady state values of TPNH/TPN$^+$ would not alter, if at the same time, oxidation of TPNH also increased two-fold.

Steroid-forming organs do not maintain high levels of stored biosynthetic intermediates beyond cholesterol, so that trophic stimulation depletes such stores of cholesterol (refs. 3–5 and unpublished observations). The synthesis of 1 mol of gestagen (progesterone and 20α-dihydroprogesterone) requires at least 2 ml. of TPNH to cleave the side chain of cholesterol[2]. It follows that the administration of ICSH has resulted in the formation of at least 2 × 0.19 μmol TPNH/g/h above levels in control tissue (no ICSH). The fact that steady state levels of TPNH/TPN$^+$ are unchanged should not obscure this. At least three possible explanations for increased formation of TPNH without change in TPNH/TPN$^+$ following administration of ICSH can be suggested. (i) ICSH increases the rate of production of TPNH to the level required to accelerate steroid production by 0.19 μmol/g/h; the additional TPNH is oxidized in the process of producing the steroids at an accelerated rate; the ratio TPNH/TPN$^+$ remains unaltered. (ii) ICSH specifically decreases oxidation of TPNH by some means not connected with steroidogenesis and this decrease equals the increase in the rate of utilization of TPNH for accelerated steroidogenesis. The equality of these two rates may reflect some controlled coupling between the two processes concerned. (iii) ICSH stimulates steroid synthesis by a mechanism not involving increased production of TPNH. Steroid synthesis could in turn generate reduction of TPN$^+$ "as it goes", by some unknown mechanism; this coupling between steroid synthesis and the reduction of TPN$^+$ would preserve steady state levels of TPNH. If the experiments reported were not carried out in steady state conditions, the data are more difficult to interpret and thus less informative.

The same considerations apply to interpretation of steady state concentrations of hormones in plasma which do not necessarily reflect the rate of production of the hormones concerned; a certain concentration can be maintained by low production with slow metabolic clearance or by high production with rapid metabolic clearance[6].

The first experimental observation of Flint and Denton[1] tells us that glucose increases TPNH/TPN$^+$ but not steroid synthesis. As they point out, the TPNH required for side chain cleavage of cholesterol must act within mitochondria. Ratios of TPNH/TPN$^+$ for the whole cell tell us nothing about mitochondrial TPNH. There is no reason to believe that enhanced glucose-6-PO$_4$ dehydrogenase activity will automatically generate intramitochondrial TPNH; *prima facie* this possibility seems quite remote. The central dilemma of the Haynes hypothesis to account for the action of ACTH on adrenal steroid synthesis[7] is the difficulty of explaining how high levels of intramitochondrial TPNH can result from increase in cytoplasmic TPNH/TPN$^+$. Simpson and Estabrook[8] suggested that malate may serve to "shuttle" reducing equivalents from cytoplasm to mitochondria. If this is so there are two possible consequences.

(i) If ICSH acts by providing TPNH for side chain cleavage of cholesterol, total cell levels of TPNH need not change after administration of ICSH, because intramitochondrial TPNH would increase at the expense of cytoplasmic TPNH. The additional reducing equivalents would be used within the mitochondria as fast as they were transported there from the cytoplasm.

(ii) Increasing cytoplasmic TPNH/TPN$^+$ by addition of glucose or by enhanced activity of glucose-6-phosphate dehydrogenase, will not *per se* increase steroidogenesis, unless the production or transport of malate is also increased to convey the extra reducing equivalents into mitochondria. The two observations of Flint and Denton can therefore be readily explained, even if ICSH stimulates steroid synthesis only by increasing reduction of TPN$^+$.

The misunderstanding revealed in the proposed interpretation of these data arises from the idea that if stimulation of steroid synthesis results from increase in TPNH/TPN$^+$, the cell establishes this stimulation by first developing a head of reductive energy followed by increased output of steroids. It could equally well be that steroid synthesis is poised ready for any increase in TPNH; reduced pyridine nucleotide would be formed more rapidly but would not accumulate. One important result of a systems approach to the control of steroid synthesis has been the demonstration of rapid return of steroidogenesis to control levels when trophic stimulation is withdrawn[9]. The sort of lag expected from the "running down" of accumulated high levels of TPNH is not observed.

Even if the cell sets up a high ratio of TPNH/TPN$^+$ which then drives steroid synthesis at an accelerated rate, it seems likely that the high levels of TPNH would soon be consumed. High levels of TPNH may not persist for 1 h after injection of ICSH.

The importance of increased production of TPNH in explaining the mechanism of action of ICSH will only become clear when we know more about the intracellular compartmentalization of pyridine nucleotides and when we can monitor continuously the redox state of TPN. TPNH may or may not be the fundamental mediator or the action of ICSH, but negative data on steady state values of TPNH/TPN$^+$ at a single time interval do not facilitate evaluation of this concept.

Chromosomes of Cancer Cells

THE reported[1] alterations in the malignant potential of a virus transformed mouse fibroblast cell line and its relationship to variations in the chromosome number seems to have a parallel in the human cervix. Our studies of the chromosome patterns seen in pre-invasive and invasive carcinomas of the uterine cervix suggest that these patterns may be an indicator of the invasive potential of the pre-invasive lesion[2]. We have proposed a theory in which we contend that the tetraploid and hypertetraploid pre-invasive lesions are less likely to develop into invasive carcinoma and that a potentially invasive lesion will have a peri-diploid component in its cytogenetic profile[3].

In human cervical cancer the differences in chromosome number may be related to the nuclear size of the component cells. Small, mixed and large cell lesions occur in both types of neoplasm[2]. It seems from our data that large cell pre-invasive lesions are cytogenetically distinct from large cell invasive carcinomas, the latter having a mean count of seventy-one compared with seventy-nine for pre-invasive cancer.

In both pre-invasive and invasive carcinoma of the cervix there is a wide distribution of chromosome number which cannot be described fully by the median[4]. We devised a statistical model to describe the total chromosome number distribution within individual lesions[3]. The use of the mean and variance to describe the component populations of the individual lesions shows a change in pattern which seems to occur between the pre-invasive lesions and invasive lesions. Pre-invasive lesions with chromosome counts in the tetraploid, quintaploid and hexaploid ranges were not represented in the invasive cancers and we suggested that a peri-diploid or peri-triploid dominance was required before invasion could take place[3]. Few examples of progression from pre-invasive to invasive cancer have been observed in human material, but an example of progression to micro-invasion with the appearance of a peri-diploid chromosome complement has been reported[5]. Present studies in this laboratory also seem to indicate that the sensitivity of invasive carcinoma of the cervix to radiotherapy may be related to variations in the chromosome constitution.

Overall, the comparison of the patterns in pre-invasive and invasive cancer of the cervix suggests that hypertetraploidy is associated with a low degree of malignancy. It seems possible, therefore, that these previously extraordinary variations in chromosome constitution are related to the progression of the individual neoplasm, but only when the entire chromosome complement is considered. The changes in the chromosome pattern which have been reported in a virus transformed cell line seem to have a clinical counterpart, particularly when the total cytogenetic data for cervical neoplasia are considered. It is also of interest that a virus (Herpes type II) has been implicated as an oncogenic agent in the human cervix[6].

Collection of Lymph from Kidneys Homotransplanted in Man: Cell Transformation *in vivo*

ALTHOUGH there have been careful studies[1-3] of the successive steps of lymphocyte sensitization by histocompatibility antigens *in vitro*, it has not yet been demonstrated directly that the same cell transformation takes place *in vivo* after a human organ allograft.

The practical problem is to devise a method of collecting a representative sample of lymph from such a transplanted organ. The lymph formed in the merino sheep kidney is drained entirely by a small number of hilar lymphatic ducts, so that cannulating one of these vessels and tying off the others allows the collection of the entire renal lymph[4]. In most other animals, including man, this is not however possible, because the renal lymphatic ducts are dispersed and not concentrated in the hilum. We have, nevertheless, succeeded in cannulating one of the renal lymphatic ducts of kidneys homotransplanted in dogs and in man. This communication concerns our attempts in man.

One way to make visible the human lymphatic ducts is to inject 1 ml. of Evans blue into the renal cortex. Three minutes later, some lymph ducts are seen on the exterior aspects of renal vessels. A ligature of vascular silk can be tied around this duct to serve as a label. Lymphatic ducts are extremely difficult to see in the ischaemic kidney, but we find they become clearly visible 10 or 15 min after transplantation. A polyethylene cannula (interior diameter 0.35 mm) filled with a saline solution of heparin can then be introduced into the duct and fixed tightly with a vascular nylon ligature. The catheter is led out through the abdominal incision.

In four recipients of kidney allografts, renal lymph collection was possible for 7, 5, 10 and 8 days after transplantation respectively. Lymphocyte outflow was measured daily. A differential count of normal lymphocytes and other cells, if any were present, was performed. Cells were studied by light and electron microscope. Tritiated thymidine incorporation was measured daily in the lymph and every second day in the blood with a scintillation counter, using 1 µCi/10^6 lymphocytes. Cellular radioautographies were performed daily.

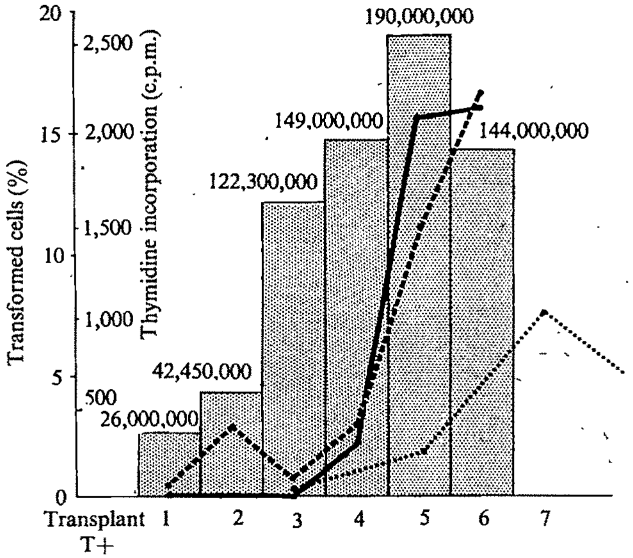

Fig. 1 Lymphocyte flow, percentage of lymph cell transformation and tritiated thymidine incorporation in lymph and in blood, following lymphatic duct drainage of an allografted kidney in man (case 1). Shaded sections, lymphocyte flow (cells/24 h); ● - - - ●, thymidine incorporation in lymph; ●—●, percentage of transformed cells; ● · · · ●, thymidine incorporation in blood.

The results in case 1 are shown in Fig. 1. This 29 yr old patient was given a kidney transplant taken from a cadaver 146 min after death. Renal ischaemia resulted in a 6 day oliguric renal failure followed by a progressive recovery. The patient received 300 mg of azathioprine, 5 ml. of antilymphocyte serum and 24 mg of betamethasone phosphate per day. The collected lymph contained 96–99% of small lymphocytes during the first 5 days. The total lymphocyte flow was successively 26 million, 42 million, 122 million, 149 million, 190 million and 144 million cells per 24 h. On days 5 and 6 there was a sudden appearance of transformed cells identical to the immunoblasts observed in mixed lymphocyte cultures and reaching 16% of the total cells. At the same time, the tritiated thymidine incorporation measurement rose from 91 c.p.m. on day 3 to 2,258 c.p.m. on day 6. Radioautographies showed a similar elevation of labelled cells. Tritiated thymidine incorporation into blood leucocytes also increased, but more slowly than in the lymph; after a peak on day 8 it decreased regularly. Coagulation stopped the lymph flow on day 7 and the catheter was removed. Case 2, in which the transplanted kidney was also taken from a cadaver, gave results similar to those observed in case 1, but the lymph flow ceased on day 5.

In cases 3 and 4 the kidney was taken from a living related donor. In case 3 (transplantation between siblings) a marked *in vitro* cell transformation (23% transformed cells) had been found in the mixed lymphocyte culture of donor and recipient cells before transplantation; the *in vivo* examination of the renal graft lymph showed essentially similar results to those found in case 1. In case 4 (parent to child transplantation) the mixed lymphocyte culture had shown no stimulation (1.6% transformed cells) and no cell transformation was found *in vivo* in the allograft lymph; neither was there any increase in thymidine incorporation. The clinical course in the latter case was remarkably uneventful.

These *in vivo* findings reinforce the suggestion that mixed lymphocyte culture may be considered "a model for allograft rejection"[5]. The similarity between the cell transformation taking place in the recipient of a human renal allograft and the cell transformation found in the *in vitro* mixed lymphocyte culture is striking. This has practical as well as theoretical importance because it suggests the immunological reaction may be studied and followed for several days in patients receiving a kidney allograft by using a daily collection of the graft lymph.

This may provide a new tool for recognizing and measuring the recipient sensitization, even in cases where the clinical signs of "rejection" are lacking or ambiguous. It also opens a new field for the *in vivo* collection and study of sensitized cells in human organ transplantation.

Effect of Thalidomide on Human Embryonic Tissues

WE wish to report results which can be used in an attempt to define the level of action of thalidomide on human embryonic tissues *in vitro*. Because it is difficult to obtain human embryonic tissues in quantities sufficient for biochemical measurements, these results are based on the morphology and histology of cultured human tissues.

The starting point for these studies was the observation[1] that the mesonephros of 2–3 day old chick embryos undergo chondrogenesis if cultured on nutrient agar, but not if it is wrapped in chorioallantoic membrane (compare ref. 2). The chondrogenic potential of the mesonephros adjacent to the appendages was greater than that of the intervening region[2]. Thus chondrogenesis seemed to be related to girdle or appendage cartilage. Indeed, chondrogenesis is enhanced in 2–3 day limb buds cultured in association with the adjacent mesonephros, but not in buds from older embryos[3].

An investigation of the effects of thalidomide on mesonephros–limb bud chondrogenesis in cultured chick tissues has shown that thalidomide inhibited mesonephric chondrogenesis, whereas 'Doriden' (a non-teratogenic analogue of thalidomide) had no effect. The inhibitory effect was clearly on the mesonephric tissue, not the limb bud tissue[3].

Like most teratogenic agents, thalidomide has its greatest effect during a restricted period of development, with the human limb this occurs during the second month of pregnancy[4].

We obtained human embryos from the Boije Clinic, Helsinki, and dissected out somites from the posterior limb region; presumptive girdle tissue from the same region; ventral spinal cord and notochord; limb mesenchyme, and the nephric tissue complex (mesonephros, metanephric bud and metanephric mesenchyme). These were cultured on nutrient agar (1% agar containing Simm's balanced salt solution (SBSS), foetal calf serum (FCS) and Coon's modification of Ham's F12 (F12X)), in the ratios 2 : 2 : 1. Foetal calf serum and F12X were obtained from Grand Island Biological Co. The liquid feeding medium used was SBSS : FCS : F12X, (2 : 2 : 1) with no supplement, with thalidomide (obtained from W. S. Merrell before court litigation began), or with 'Doriden' (Ciba).

Thalidomide and 'Doriden' were used in a concentration of 0.8 mg/100 ml. The nutrient medium was too dense to allow spectrophotometric measurements of the thalidomide solution to check the concentration after the culture period. The half life of thalidomide *in vivo*, or at *p*H 7.4 at 37° C is reported to be 2–3 h (ref. 5 and personal communication from Schumacher *et al.*). The maximum aqueous solubility of thalidomide is 20–30 µg/ml.

After feeding with the liquid nutrient medium, tissues were covered with mineral oil ('Klearol'), and cultured at 37° C in 5% CO_2 : 95% air, in a humidified incubator. Cultures were kept for 3 days, when cartilage was visible in the controls, and then fixed in acetic acid : absolute ethanol (1 : 3).

The cultures were: (*a*) mesonephros; (*b*) mesonephros plus adjacent limb bud; (*c*) limb buds; (*d*) metanephric mesenchyme; (*e*) metanephric bud; (*f*) metanephric bud recombined with metanephric mesenchyme; (*g*) embryonic somites, and (*h*) embryonic somites plus a section of the ventral spinal cord or of the notochord. Although many cells died in older cultures, there was enough viable tissue in 3 day cultures to ascertain tissue differentiation.

Metanephric mesenchyme from 6 week old embryos formed tubules only if cultured in association with the ureteric bud, which corroborates Grobstein's findings[6] with mouse embryos. Embryonic somites from 6–7 week old embryos formed small amounts of cartilage if cultured alone, but significantly more in association with the embryonic spinal cord or notochord. These results agree with findings using embryonic chick tissues[7].

Cultures of mesonephros from 6–8 week embryos consistently formed small amounts of cartilage matrix, as shown by staining with Alcian blue, which is diagnostic for glycosaminoglycans. Six experiments were performed with embryos between 6 and 8 weeks old, as judged by size, or the stage of development of tissue fragments found in the debris. The mesonephros was dissected free of adhering tissues, and one side was cut into 1 mm³ pieces and cultured in the presence of thalidomide. The other half was similarly dissected, and cultured either in plain nutrient medium, or with 'Doriden'.

Table 1 Qualitative Scoring for Cartilage Matrix in Cultures of Human Mesonephros

Case No.	Age (weeks)	Treatment	Matrix scoring Range	Matrix scoring Cumulative sum
056–5	6+	Thal.	2–3	7
056–7	6+	'Doriden'	3–5	14
056–6	6+	Thal.	2–3	6
056–8	6+	'Doriden'	3–4	11
060–3	7+	Thal.	1–2	4
060–4	7+	'Doriden'	2–3	8
073–1	8+	Thal.	1–3	5
073–2	8+	'Doriden'	1–2	4

The range represents the minimum and maximum values for the three parameters used (amount, density and maturation of matrix). The cumulative sum represents the total for all three parameters. Scoring was from 1 (minimum) to 5 (maximum). The tissues were dissected from 6–8 week old human embryos and cultured on F12X nutrient agar for 3 days. Thalidomide and 'Doriden' were at a concentration of 0.8 mg/100 ml. of medium.

The results are shown in Table 1 and Fig. 1. Cartilage matrix was scored on histological slides, and the following assay procedures were used. The tissue sections stained with Alcian blue were examined independently and "blind" by four scientists and scored on a scale from 1 to 5 with respect to the relative amount of cartilage matrix (that is Alcian blue positive material), the density and the maturation of the matrix. The lowest values represent the least chondrogenic differentiation, and the cumulative sum represents the total of the three parameters (amount, density, maturation) indicating the degree of chondrogenesis. Table 1 shows that chondrogenic inhibition by thalidomide was most noticeable on the younger embryos (6–7 weeks old). The older the mesonephros, the less cartilage formed and the difference between the experi-

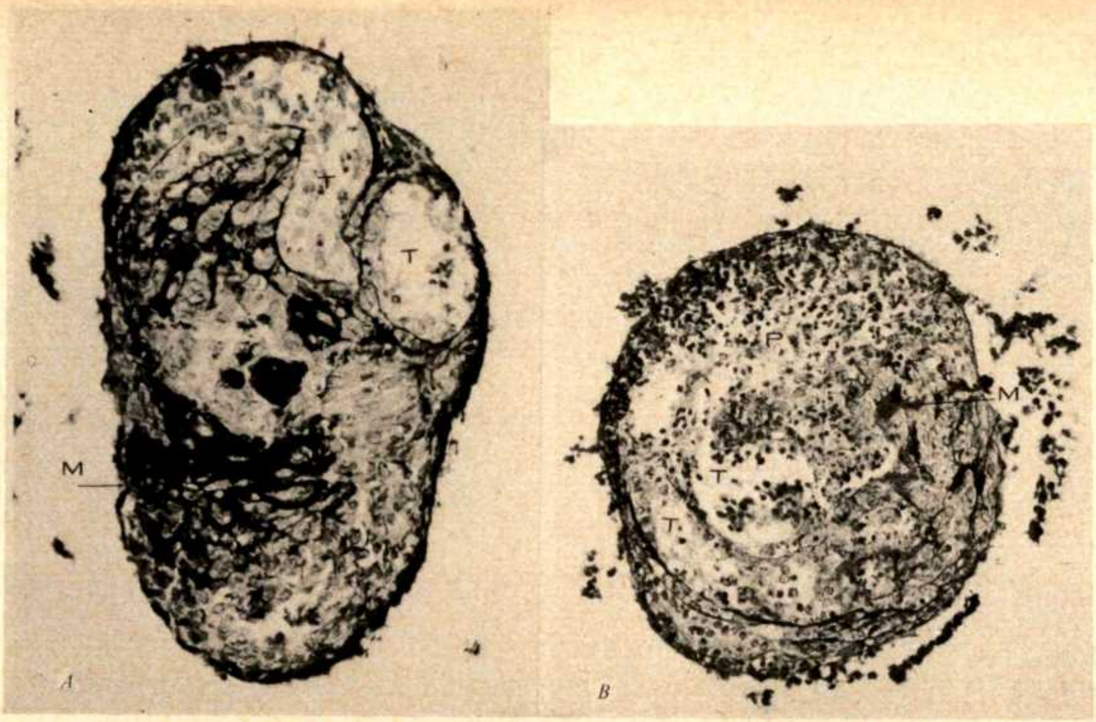

Fig. 1 *A*, Cultured human mesonephros from a 6 week old human embryo treated with 'Doriden'. The matrix (M) appears black in the photograph and tubules (T) are evident. (Alcian blue × 200.) *B*, Contralateral mesonephros from the same embryo, treated with thalidomide. The matrix is much less prominent, and the tubules are still evident. Pycnosis (P) is visible. (Alcian blue × 100.)

mentals (thalidomide) and the controls ('Doriden') was negligible.

Thus tissue associated with the human mesonephros at an early stage of development (6–7 weeks of age) seems to form cartilage in tissue culture. As the embryo ages, the amount of cartilage diminishes. The scoring for cartilage matrix in 6 week old tissues cultured in 'Doriden' ranged from 3 to 5 for the three parameters, with a cumulative sum of 14 (Table 1). For 8 week old tissues the corresponding values were 1–2 and 4, indicating significantly less matrix. These results agree well with the results obtained with chick mesonephros[3]. In addition, the tissues treated with thalidomide showed a significant decrease in matrix formation in 6 week old tissues, a similar decrease in 7 week old tissues, but no difference in 8 week old tissues. This again is similar to chick mesonephros[3].

When human limb buds from these embryos were grown in culture, cell death was more rampant, but nevertheless cartilage formed and there was no noticeable effect of thalidomide. None of the other chondrogenic tissues were inhibited.

These results suggest that a major site of action of thalidomide on limb-related chondrogenesis in human embryos is tissue associated with the embryonic mesonephros at a certain stage of development.

Rabbit Blastocoele Perfusion Technique

Trophoblast cells must play a significant role in the movement of solute and water into the blastocoele[1]. The epithelial trophoblast (Fig. 1*A*), exposed on one side to the uterine environment and on the other to the blastocoele fluid, appears structurally and functionally similar to other solute and water transporting organs with epithelial cells which separate the blood stream from body cavities[2]. There is evidence for active ionic transport across the rabbit trophoblast[2–5], perhaps in connexion with the accumulation of blastocoele fluid[2,4].

The active transport components of the trophoblast membrane could be studied by techniques which have been applied successfully to various epithelial membranes, if the composition of the blastocoele fluid could be controlled. We have therefore investigated this problem. My first approach was to form a flat sheet of cells out of the blastocyst which could be placed between two fluid chambers, similar to the method used to study frog skin epithelium. My second method was to perfuse the blastocoele cavity using glass pipettes. Perfusion methods have been developed for various tissues, such as the squid giant axon[6], marine algae[7], and isolated renal tubules[8]. After many attempts at both approaches, the latter proved to be the better solution. I now describe a successful method and report electrical parameters of the 6 day rabbit blastocyst under continuous-flow perfusion.

Blastocysts were flushed from the uteri of naturally mated New Zealand rabbits. One of them (2–3 mm, average diameter) was secured in a special environmental chamber[4] and glass perfusion pipettes (40–60 μm tip diameter) were inserted into

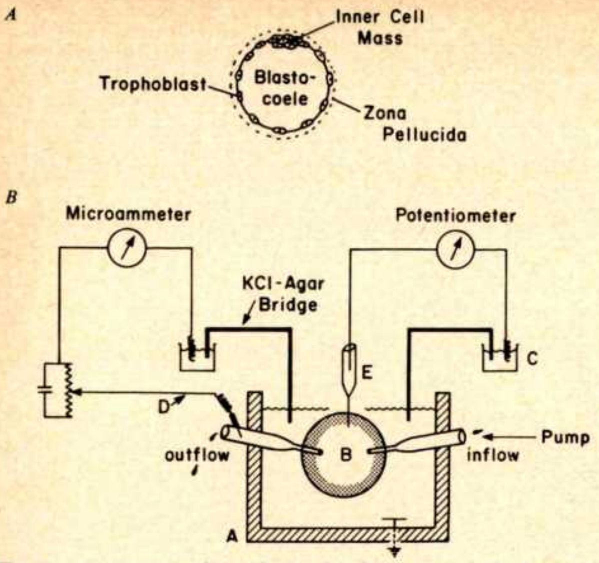

Fig. 1 *A*, Cross section of a 6 day blastocyst. *B*, Assembly for internal perfusion and electrical measurements of the blastocyst. A, Chamber used to secure embryo and maintain constant temperature, humidity, and gas phase (5% CO_2 in air); B, blastocyst; C, Ag-AgCl-KCl half cell; D, Ag-AgCl wire used for applying outside EMF; E, microelectrode.

opposite sides of the blastocyst. All manipulations were carried out using micromanipulators under a dissecting microscope.

The two chief difficulties in the perfusion of the blastocoele are: (1) how to penetrate the zona pellucida and trophoblast with pipettes which are both large enough in tip diameter to allow relatively low resistance to perfusion flow, and small enough not to cause the embryo to collapse when penetrated; (2) how to prevent leaks at the junction between the trophoblast and the pipette.

The solution was first to penetrate the tough inert zona pellucida and the trophoblast layer with a micropipette (tip diameter <1 µm), and then advance the micropipette into the blastocoele cavity until the shank of the micropipette was of similar diameter to that of the inflow pipette to be used. The micropipette was then withdrawn, leaving a small wound in the trophoblast wall and a small opening in the zona. The inflow pipette, filled with medium, connected to the inflow reservoir and clamped, was then inserted through the opening in the zona and the wound in the trophoblast without collapse of the blastocyst and with very little loss of blastocoele fluid. Using the same procedure, the outflow pipette, filled and connected to the outflow reservoir, was inserted on the opposite side. Any fluid loss from the blastocoele could now be replaced by opening the input side of the perfusion system and pumping in fluid while maintaining the output side closed. Once the perfusion pipettes were in place, a microelectrode was inserted into the blastocoele cavity for electrical measurements. The trophoblast epithelium was then allowed to seal around the three inserted pipettes (Fig. 2).

Surprisingly, the trophoblast epithelium adhered naturally to the glass pipettes forming a tight seal. By regulating the inflow perfusion rate by adjusting the pumping speed and the outflow rate by regulating the height of the outflow reservoir in relation to the chamber, the blastocyst could be maintained at its original volume without leakage around the trophoblast-pipette junction. By regulating inflow and outflow rates in this manner, the blastocoele contents could all be removed so that the cavity collapsed, and then replaced almost at will. Leaks around the pipettes could be detected microscopically and electrically. If perfusion pressure were increased, the blastocoele cavity expanded, causing the junction between the trophoblast and the pipette to be broken and the potential to decrease rapidly to near zero. Finally, to assess the possible leakage of the perfused blastocyst, ^{14}C-sucrose was added to the inflow reservoir and the outside solution was tested for the appearance of radioactivity. In sixteen collections in four preparations no activity was detected in the bathing solution, showing that a sensitive perfusion control system eliminated leakage problems. The perfusion procedure was started by quickly replacing the contents of the blastocoele with perfusion solution, after which a constant perfusion rate was maintained. Flow rates averaged between 2 and 3 µl./min. In a blastocyst of 2.5 mm average diameter there would be a complete exchange of solution about every 3–4 min.

Table 1 Electrical Properties of the Perfused Rabbit Blastocyst

Blastocyst	Time (min)	E_t* (mV)	I_{sc} (µA/cm²)	R (Ω cm²)
1	210	−6.2	5.2	1,204
2	70	−4.4	2.9	1,509
3	90	−4.8	2.8	1,783
4	150	−4.4	3.8	1,237
5	70	−5.7	3.0	2,218
6	110	−4.3	3.6	1,824
7	90	−6.6	6.5	1,099
8	180	−8.0		
9	180	−9.7		
10	180	−5.7		
11	90	−8.2		
12	130	−4.1		
Mean ± s.e.		−6.0 ± 0.52	4.0 ± 0.52	1,553 ± 154

* Blastocoele cavity negative with respect to external medium.

E_t and I_{sc} were recorded at 10 min intervals throughout each experiment.

The potential difference (E_t) across the trophoblast epithelium, short-circuit current (I_{sc}) and resistance (R) are given along with the time during which E_t and I_{sc} remained relatively constant. The perfusion and bathing medium were Eagle's containing 20% calf serum.

When experience with the technique permitted a high frequency of successful perfusion, the electrical properties of the epithelial trophoblast were studied. The potential difference (E_t) and short-circuit current (I_{sc}) across the trophoblast wall were measured as described by Ussing and Zerahn[9] with the circuit shown in Fig. 1*B*. Eagle's medium containing 20% calf serum was used for the perfusion and outside bathing media. The trophoblast membrane behaved as a simple linear resistor, and so resistance measurements were computed from the ratio of open-circuit potential to short-circuit current (Fig. 3). The resistance of the bathing solution measured without the blastocyst in position was always less than 40 Ωcm.

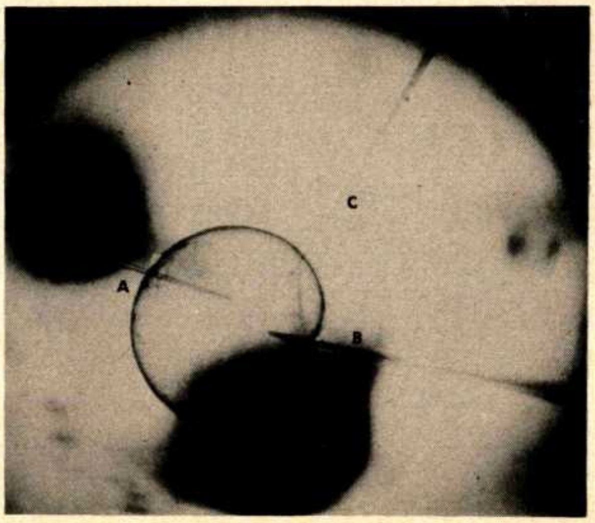

Fig. 2 Perfusion of a 6 day rabbit blastocyst during measurement of the electrical properties of the trophoblast wall. A, Inflow perfusion pipette; B, outflow pipette; C, microelectrode. The two dark spots in the photograph are caused by two gaskets at the bottom of environmental chamber.

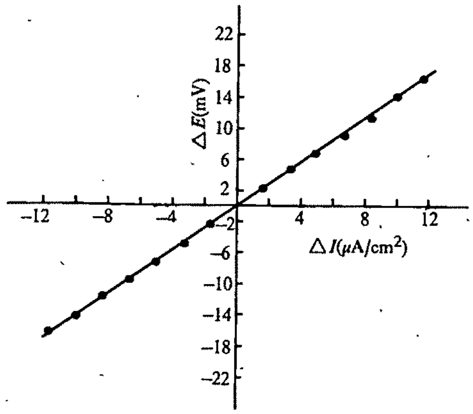

Fig. 3 A typical current-voltage graph for a perfused rabbit blastocyst. The origin of potential is −4.4 mV. Negative values of ΔE represent hyperpolarized potentials, produced by current passing inward across the trophoblast.

Table 1 shows the electrical properties of continuously perfused rabbit blastocysts. The average potential across the epithelial trophoblast (±s.e. of the mean), of twelve blastocysts under continuous perfusion with identical solutions on both sides, was −6 ±0.52 mV, whereas the value for twenty-three non-perfused embryos was −11.1±0.79 mV. The average specific membrane resistance of seven blastocysts measured under continuous perfusion was 1,553±154 Ωcm² and compares with 2,188±202 Ωcm² averaged from fifteen non-perfused embryos. In many cases, a non-perfused and a perfused blastocyst were obtained from the same rabbit. The average short-circuit current recorded in seven perfused blastocysts was 4±0.52 μAmp/cm² or about 0.15 μequiv./cm²/h. When both sides of an epithelial membrane are bathed with identical solutions, the short-circuit current represents the net active movement of ions across that membrane[9]. The time during which both E_t and I_{sc} remained relatively constant averaged 129 min lasting 70–90 min in five embryos and 110–210 min in seven others (Table 1). Some embryos may have maintained steady electrical properties longer than the times shown (180–210 min) for these experiments were arbitrarily terminated. Three blastocysts, which had their zonae pellucidae mechanically removed before perfusion, showed electrical properties similar to those with intact zonae. A technique has therefore been developed which will permit the study of transport phenomena across a mammalian embryonic membrane, using methods which are well documented for other epithelial membranes.

Limited Synergism between Rat Thymus and Mouse Bone Marrow

IN a number of experimental systems[1] it has been shown that thymus and bone marrow-derived cells can cooperate in the production of humoral antibodies. In some instances this synergism has been demonstrated when the interacting cells are antigenically similar but in other experiments allogeneic cells have been found to cooperate. We have now demonstrated cooperation between rat and mouse cells. A two-step experiment was performed, following the design of Miller[2]. Rat or mouse thymus cells were introduced with antigen into irradiated recipients. The donor cells were collected and injected into secondary host mice. The details of these experiments and their results are as follows.

Twenty adult RK mice, 10–12 weeks old, were given 900 r. of total body irradiation from a ^{60}Co source. Ten were injected with 2×10^7 mouse thymus cells plus 0.1 ml. of SRBC at 20% (group 1), and ten were injected with 2×10^7 rat thymus cells plus 0.1 ml. of SRBC at 20% (group 2).

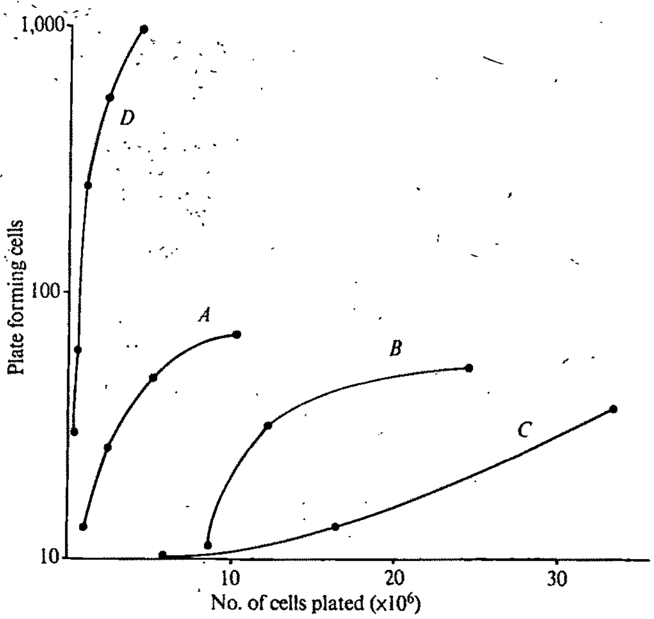

Fig. 1 Effect of mouse and rat thymus on the immunocompetence of mouse bone marrow cells (see text). Group *A* lethally irradiated mice repopulated with mouse thymus and mouse bone marrow cells; group *B*, lethally irradiated mice repopulated with rat thymus and mouse bone marrow cells; group *C*, lethally irradiated mice repopulated with mouse bone marrow cells; group *D*, unirradiated control mice given only SRBC.

Five days later another twelve RK mice, 10–12 weeks old, were given total body irradiation, and then three were injected with $1\cdot5\times10^6$ cells from group 1 pooled spleens plus 2×10^7 mice bone marrow cells and 0.1 ml. of SRBC at 20% (group *A*), three were injected with 1.5×10^6 cells from group 2 pooled spleens plus 2×10^7 mice bone marrow cells and 0.1 ml. of SRBC at 20% (group *B*), and three were injected with 2×10^7 mice bone marrow cells and 0.1 ml. of SRBC at 20% (group *C*). As controls three irradiated and three non-irradiated mice (group *D*) were immunized with 0.1 ml. of SRBC at 20%.

Six days later we counted plaque forming cells against SRBC—of pooled spleens of the different groups—by the Jerne technique[3]. All cellular suspensions were prepared in cold phosphate buffer saline, P 7.4, and injected intravenously within 3 h of the irradiation.

Fig. 1 shows that rat and mouse cells can cooperate, although not as efficiently as mouse–mouse combinations. The mechanism of cooperation is not understood but if it involves recognition of organ specific surface antigens it seems that these may be recognized across genetic barriers.

Cytotoxic Antibody for Epithelial Cells in Human Graft versus Host Disease

THE transplantation of immunocompetent cells into an immunologically suppressed individual frequently results in a syndrome believed to be due to an immune reaction of the grafted cells against the host. In man this graft versus host (GVH) reaction prominently involves the skin, gastro-intestinal tract and liver, and is characterized pathologically by lymphoid cell infiltrates, basal cell layer destruction and dyskeratosis[1]. The mechanism by which the GVH reaction damages epithelial structures has not been studied in man. Streilein and Billingham have studied a GVH-like reaction prominently involving the skin in hamsters and have made a number of observations pertinent to the mechanism of the GVH pathology[2,3]. One of their observations, the finding of a cytotoxic factor against hamster and rat epidermal cells in the serum of hamsters with GVH-like skin lesions stimulated us to investigate this in man. We have found in human patients with GVH an IgM antibody which is cytotoxic for epithelial but not lymphoid cells.

We studied sera from recipients of bone marrow transplants being cared for on the Leukemia Service of the National Cancer Institute. Of eight patients who underwent bone marrow transplants from their HL-A identical siblings, four developed clinical manifestations compatible with GVH, and in three of these the diagnosis was confirmed pathologically[4–6]. Sera were tested for cytotoxicity using a $^{51}\mathrm{Cr}$ cytotoxicity technique[7]. Target cells labelled with $^{51}\mathrm{Cr}$ and serum were incubated for 10 min before addition of rabbit complement, and then for 90 min at room temperature. A given serum was considered to be cytotoxic if it caused a minimum of 15% more $^{51}\mathrm{Cr}$ release from the target cells than normal human serum. The target cells used were monolayer cultures of HeLa and Hep-2 cells, both epithelial cell lines derived from a squamous cell carcinoma of the cervix and a squamous cell carcinoma of the larynx respectively. Lymphoid target cells were from lymphoid cell lines maintained in long term culture.

Reactivity of one patient's serum with epithelial and lymphoid cells at various intervals after transplantation is shown in Fig. 1. Pretransplant serum contained no cytotoxicity against either lymphoid or epithelial cell lines. During the third week after grafting, however, his serum contained cytotoxicity against the epithelial cells. No cytotoxic reactivity against lymphoid cells was present. The appearance of epithelial cytotoxicity coincided with the development of a rash, diarrhoea, jaundice and desquamation, all of which seemed compatible with GVH reaction. A skin biopsy on the twentieth day after the transplant as well as autopsy findings in skin, liver and intestine on the 32nd day were all compatible with GVH disease.

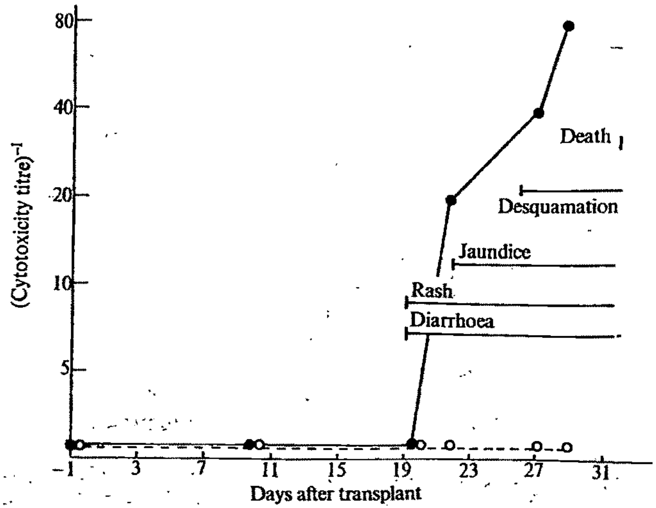

Fig. 1 Cytotoxic activity of serum from a patient with GVH following bone marrow transplantation. The solid line shows reactivity against epithelial (HeLa and Hep-2) cells; the broken line reactivity against lymphoid cells. The onset of each manifestation of GVH is also shown.

Two further patients had clinical evidence of GVH which was confirmed pathologically, and a third had mild symptoms compatible with GVH, although the diagnosis was not confirmed pathologically. In each of these patients, serum cytotoxicity against epithelial but not lymphoid cells appeared coincident with the development of rash and other manifestations of GVH. In contrast with sera from patients with GVH, sera from four transplant recipients in whom there was graft take but no GVH were not cytotoxic for epithelial cells. Similarly, sera from fifteen patients with acute lymphocytic leukaemia who did not receive marrow transplants, and sera from fifteen normal individuals were not cytotoxic for epithelial cells (Table 1).

Table 1 Antiepithelial Activity of Sera from Patients with GVH

Epithelial cell antibody (No. positive/No. tested)	Patient group studied
3/3	Clinical GVH, confirmed histologically
1/1	Probable GVH, not confirmed histologically
0/4	Graft take without evidence of GVH
0/15	ALL not grafted
0/15	Normal individuals

Sera were from non-affected transplant recipients, non-transplanted leukaemics, and normal individuals. ALL, acute lymphocytic leukaemia.

The cytotoxic factor was characterized with respect to molecular properties and specificity. The cytotoxicity of the sera for epithelial cells was complement dependent. Reactive sera from two of the patients were fractionated by gel filtration through 'Sephadex G-200'. The cytotoxic activity was found in the excluded protein peak which contained IgM but not IgG or IgA when screened by Ouchterlony agar diffusion using specific antisera. Treatment of cytotoxic sera with 0.1 M 2-mercaptoethanol destroyed the ability of the sera to lyse epithelial cells. These results provide evidence that the cytotoxic factor in these patients with GVH disease is an IgM antibody.

To investigate the possibility that the sera were reacting against an HL-A antigen, they were screened against a panel of lymphocytes from ninety individuals; no pattern of HL-A reactivity was observed. In addition, absorption of the sera with lymphocytes having a broad range of HL-A alloantigens did not remove the cytotoxicity for the epithelial cells. Absorption of the reactive sera with one epithelial cell line removed reactivity for the other. Thus it seems that the GVH antibody is not directed against HL-A antigens but has specificity for epithelial cells. A further indication of this specificity is the finding that the sera failed to react with tissue culture hepatocytes and fibroblasts.

The pathogenesis of the GVH reaction is unknown; but the observation that patients with this disease have an antibody directed to epithelial cells suggests several mechanisms for this reaction. The antibody we are detecting may be directed against minor histocompatibility antigens that are expressed only as epidermal specific antigens not detected by the usual HL-A matching techniques. Boyse *et al.* have presented data suggesting similar antigens in mice[8]. Alternately, it may be that damage initially produced in the skin by the GVH reaction exposes hidden epidermal antigens and these then provoke the formation of "autoantibodies" against epithelial cells. A third possibility is that impaired immune function in the grafted recipient predisposes to certain viral infections, and that alteration of epidermal cell surface antigens induced by virus, or cross-reactivity between viral and epidermal antigens accounts for the antibody detected in these patients. Further investigation of these and other possibilities may provide information about the importance of tissue specific non-HL-A antigens and antibodies in the processes of graft rejection and in the pathophysiology of the GVH reaction.

We thank Dr E. S. Henderson, Medicine Branch, and Dr R. G. Graw, Human Tumor Cell Biology Branch, National Cancer Institute, for the opportunity to study sera from their patients. Miss B. A. Plocinik performed cytotoxicity assays.

Teratocytes as a Means of Resistance to Cellular Defence Reactions

I HAVE suggested that teratocytes, the giant cells which develop from the trophamnion of many parasitoid Hymenoptera, serve as a means of resistance to the defence reactions of insect hosts[1]. These cells are relatively small when they dissociate from the embryonic membrane, but as they become distributed in the blood of the host they expand to as much as 3,000 times their original volume. Their growth is achieved by the absorption of nutrients from the host's blood and I suggested that the consequent depletion of materials in the haemolymph would impede or inhibit haematopoiesis and prevent an effective haemocytic reaction to the young parasitoid.

Evidence supporting the hypothesis has been obtained in the course of experiments designed for another purpose. Eggs and larvae of the ichneumon wasp *Nemeritis canescens*, which does not produce teratocytes, were implanted in caterpillars of *Eucosma hohenwartiana* collected out of doors from heads of knapweed, *Centaurea nigra*. In healthy caterpillars the parasitoid was promptly killed by cellular defence reactions. Against all expectation, one larva of *Nemeritis* was found feeding and developing without encapsulation when it was 5 days old. The caterpillar containing this individual, however, was also infected by a braconid parasitoid, and its blood contained numerous teratocytes about 50 μm in diameter. In two caterpillars infected by wild parasitoids which had not produced teratocytes, the *Nemeritis* was encapsulated as it was in healthy hosts.

Three more examples of this phenomenon have recently been observed in caterpillars of *Chilo phragmitellus* collected from reeds at Wicken Fen. When eggs of *Nemeritis* were implanted in healthy caterpillars of this species, they were encapsulated, melanized and killed; only two hatched, and the larvae were then promptly destroyed in the same way. Three caterpillars in which eggs were implanted turned out to be already parasitized by gregarious braconids, probably *Apanteles ferrugineus*, which had produced many teratocytes. From these three hosts, and from them only, larvae of *Nemeritis* 5 days old were retrieved alive, feeding and apparently developing normally, without any trace of a haemocytic defence reaction.

These observations show that teratocytes are indeed a means of resistance to the cellular defence reactions of insects, and that the protection they afford is not restricted to the species of parasitoid that produces them but extends to other species. Since their action is not specific, attrition of the host is most likely to be the mechanism by which teratocytes have their protective effect.

I thank Mr J. A. Lade for help with the collection of caterpillars.

Cellular Basis for Immunologic Memory

AFTER exposure to an antigen resulting in a primary immune response, experimental animals and human subjects possess the ability to react specifically and in accelerated fashion to a second exposure to the same antigen. This immunological memory presumably involves specific cells, but it is not known whether it involves generation of an increased number of cells or increased synthetic (or some other) ability in individual cells. Nobody has yet identified a cell which was generated by a previous contact with a specific antigen. Lymphocytes present in the circulation of rats have been shown to carry memory[1], and recent work has established that many such cells are thymus-derived and important in many aspects of the immune response[2,3]. Because they are long lived and constantly re-circulating throughout the peripheral lymphoid organs, thymus-derived cells make ideal candidates for the carriage of memory. Indeed, memory can be diminished by killing cells in this sub-population[4].

Exposure to an antigen results in a burst of mitosis in the lymphoid organs, and at least initially many of the cells in mitosis are thymus-derived[5]. Moreover, these cells respond

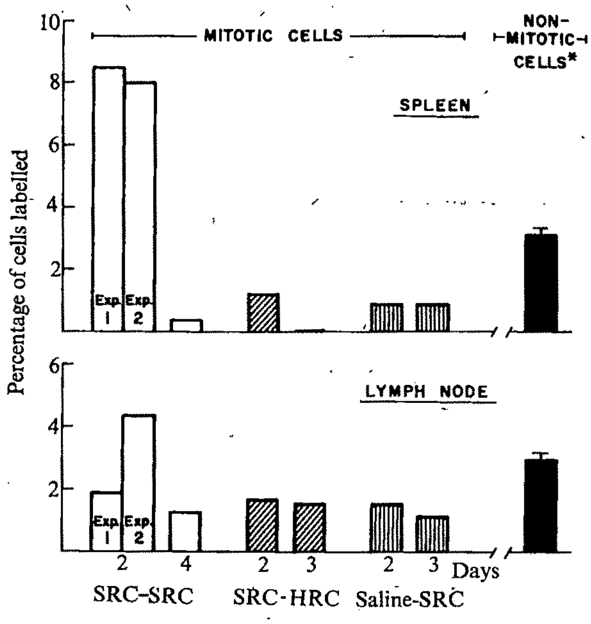

Fig. 1 Percentages of labelled mitotic and non-mitotic cells in spleen and mesenteric lymph nodes following secondary challenge. Results of two experiments are shown. The results are pooled from all the groups for they were all quite similar. The bar indicates the standard error obtained from meaning the seven groups.

with an accelerated burst of mitoses in the secondary response[3]. The peak of the mitotic response to sheep red cells (SRC) occurs on day 3 in the primary response and on day 2 in the secondary. The role of the mitosis is unknown, but it may involve the generation of specific cells some or all of which are destined to carry immunological memory. We have investigated this possibility by isotopically labelling cells synthesizing DNA in a primary response and observing the numbers of such labelled cells which responded mitotically to a second antigenic challenge. In doing this we took advantage of the work of Davies *et al.*[3,5], which clearly delineates the periods of peak mitotic activity of thymus-derived cells in mice following primary and secondary antigenic challenge. Thus we administered label for 4 days immediately after sensitization with SRC and re-stimulated with this antigen 3 weeks later. At this time we could expect continually dividing cell lines to have lost their label by dilution, while non-dividing cells would not. After a course of labelling with ^{3}H-thymidine similar to that described here, a population of heavily labelled lymphocytes is found in the spleen and lymph nodes of rats which diminishes in numbers very slowly with time[6–9]. By 21 days after cessation of labelling, when the initial rapid loss of label subsides, only a small population of heavily labelled cells persists[6–9].

Adult CBA mice received either 5×10^8 SRC or saline intraperitoneally, followed by injections of ^{3}H-thymidine every 6 h for 4 days (total dose = 7 μCi of 17.8 Ci/mmol specific activity of ^{3}H-thymidine/g body weight). Two groups of four mice, one immunized and one control, were given colcemid 3 h after the last thymidine injection. These animals were killed 1.5 h later and their spleens and mesenteric lymph nodes were removed. These tissues were divided roughly equally—half was used for tissue sectioning and the other processed by Ford's method[10] to give mitotic spreads. All other mice were challenged intraperitoneally with either 5×10^8 SRC or the same number of horse red cells (HRC) 3 weeks after primary immunization. On the second, third and fourth days after challenge, groups of three or four mice were killed and their spleens and lymph nodes processed in the same manner. All sections and spreads were dipped in diluted Kodak NTB3 nuclear track emulsion, exposed for 3.5 weeks, and developed in Kodak D19. Sections were stained with 0.1% toluidine blue and spreads with 2.0% aceto-orcein. The spreads were scored in a "blind" fashion by four persons, at least 1,500 non-mitotic nuclei and 300 mitoses being counted in each experimental group. Grain counts were performed in individual nuclei.

In an additional control experiment, two groups of six mice were immunized with 5×10^8 SRC intraperitoneally and one of these groups was given ^{3}H-thymidine as described above. All animals were bled weekly and then challenged after 3 weeks with 5×10^8 SRC and bled 5 days later. The immune response, assessed by haemagglutination titrations, was not altered by the injections of isotope.

Table 1 shows the distribution of label in the spleen cells of immunized and non-immunized mice killed immediately after the cessation of labelling (day 4). It can be seen that animals given SRC contain nearly twice as many labelled cells as control animals. In tissue sections, 4 days after the primary antigenic stimulus, many more labelled large lymphoid cells were present in the paracortical zones of mesenteric lymph nodes and the splenic white pulp than in animals given label but not antigen. There was also a diffuse increase in labelled reticulum cells in the marginal zone and red pulp of the spleen.

After specific challenge, that is, a secondary injection of SRC, very much greater numbers of labelled cells were found in mitosis in the spleens of animals at the peak of the mitotic response of thymus-derived cells[3] than were found in the spleens of animals originally given SRC and now challenged with HRC, or animals undergoing a primary immune response to SRC (Fig. 1). For the purpose of this communication a labelled nucleus is one which contained more than ten grains, although the average number of grains/labelled cell was less than seen immediately after the cessation of labelling. The numbers of labelled non-dividing cells in each of these groups did not differ significantly. Only in the group undergoing a secondary response to SRC was the proportion of labelled cells in mitosis greater than the proportion of labelled non-dividing cells. In spreads prepared from the mesenteric lymph nodes, a specific response of lower degree was observed in only one of the two experiments (Fig. 1). In histological sections of the spleen, labelled mitoses were limited to the white pulp. None was found in the germinal centres, and tingible bodies were also unlabelled. The labelled, non-dividing cells of the marginal zone and red pulp were equally numerous in specific animals and controls. In the lymph nodes, labelled mitotic cells were limited to the paracortical lymphoid tissue. By 4 days, when the mitotic activity of thymus-derived cells is over[3], labelled mitoses could no longer be found in either spreads or sections.

These results indicate that cells from the long lived popula-

tions, which are stimulated to synthesize DNA by contact with antigen, enter a resting phase until stimulated to re-enter division by secondary exposure to the same antigen. By definition these would be memory cells. They apparently correspond to Mitchell and Miller's "educated T lymphocytes"[2], for they were only observed at a time when the mitotic response of thymus-derived lymphocytes is maximal[3]. We are currently seeking direct experimental proof of their identity. Previous attempts to establish this point[11] have failed, perhaps because of the use of *Salmonella* antigens, which are poor stimulators of thymus-derived cells[12]. Our finding implies that cell replication may serve as a means of enlarging and/or altering the pool of thymus-derived cells capable of reacting with certain antigens. Replication may not, however, be essential to the helper function of these cells[13].

At the peak of the secondary response to SRC 30–40% of the cells in mitosis in the spleen are thymus-derived[3]. Thus we were initially surprised to find only 8–9% of the spleen cells responding mitotically to a second injection of antigen which showed evidence of having responded in the earlier primary response. It is important to remember that the work delineating the time and magnitude of the response of thymus-derived cells to antigen was carried out in irradiated, thymus-grafted mice. Thus it is possible that there may be some differences in normal mice. If there should be any significant differences, however, there would probably be an increase of thymus-derived cells responding in normal mice. Davies *et al.* have shown that increasing the number of reconstituting thymus grafts up to a point increases the number of peripheral thymus-derived cells[3]. This increase does not, however, alter the percentage of thymus-derived cells responding to antigen in lymph nodes nor does it change the timing of their response. It is possible that some thymus-derived memory cells lost their label through division after the period of labelling. We are investigating the possibility of recruitment of thymus-derived cells by other thymus-derived cells responding specifically. The small number (0–1%) of labelled cells found in control animals may be due, at least in part, to the emergence and subsequent response of a few thymus-derived cells which were undergoing division in the thymus at the time of thymidine administration.

The chief conclusion we should like to draw from this experiment is that one result of the DNA synthesis which follows primary antigenic stimulation is the generation of memory cells. The ability to identify these cells should be of value in characterizing them further.

R. K. G. is a recipient of a US Public Health Service Career Development Award. The work was supported by US Public Health Service grants from the National Cancer Institute, the National Institute of Allergy and Infectious Diseases and an American Cancer Society sub-grant. Polychlorinated Biphenyls: Photolysis of 2,4,6,2′,4′,6′-Hexachlorobiphenyl

MANY aromatic organochlorine compounds are readily utilized or otherwise decomposed by a number of specific microorganisms. In the environment, however, these compounds are relatively stable and resistant to general microbial breakdown. For many of these compounds photochemical degradation, induced by the ultraviolet content of the Sun's light, may be a major pathway of decomposition.

Because a large number of pesticides contain a chloroaromatic moiety as a primary structural feature, considerable attention has been paid to the photolysis of these compounds[1–7]. Photochemical decomposition of chlorobiphenyls may be a significant process in the environment because they absorb in that region of the ultraviolet (ref. 8 and our unpublished demonstrations) which is available in natural conditions (compare ref. 1) from sunlight.

Commercially available polychlorinated biphenyls (PCB) for example 'Aroclor', consist of a complex mixture of chlorinated biphenyls which can be resolved into more than fifty peaks by gas chromatography on 'Scot columns' (private communication from D. J. Sissons and G. M. Telling). As it is difficult to correlate data from such a complex mixture we have synthesized a series of isomeric di, tri, tetra, penta, hexa, octa and decachlorobiphenyls to facilitate fundamental studies on analytical, biological and chemical aspects of PCB (manuscript in preparation). We have also shown that all these compounds give strong molecular ions on electron

§ Corresponding to starting material.

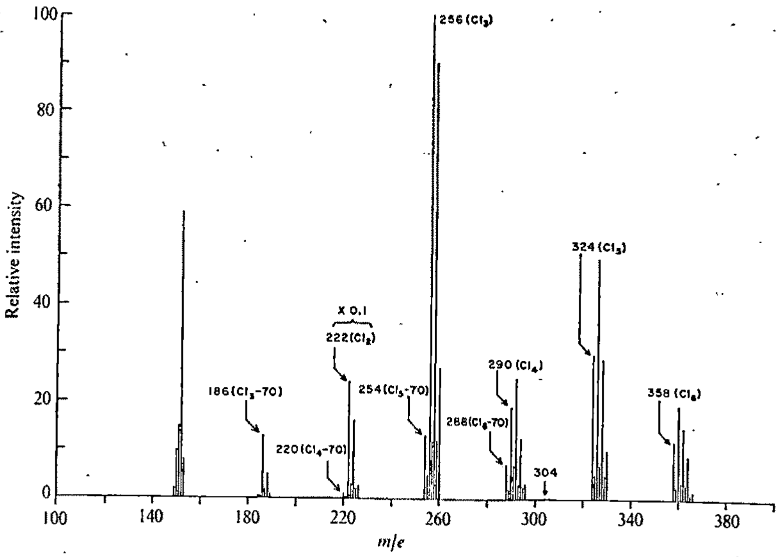

Fig. 1 70 eV mass spectrum (DuPont/CEC 21–110B instrument). The temperature of the sample, controlled independently from the source temperature[10], was 40° C. The intensity of ions corresponding to the components ($Cl_6 = C_{12}H_4Cl_6$, $Cl_5 = C_{12}H_5Cl_5$, and so on) in the mixture varies with sample temperature. Each isomer shows an M^+-70 ion as the most important fragment. These ions are indicated as Cl_6-70, Cl_5-70, and so on.

impact, followed by less intense ions resulting from successive loss of Cl and/or HCl (manuscript in preparation). As the general formula for PCB is $C_{12}H_{10-x}Cl_x$ the molecular ions of individual isomers are thus readily recognized in a mass spectrum of a mixture of these compounds (compare ref. 9).

We now wish to report the photochemical behaviour of 2,4,6,2′,4′,6′-hexachlorobiphenyl. A sample of 25 mg of this compound in 2.0 ml. of hexane was irradiated at λ_{max} 3100 Å for 100 min. Thin-layer chromatography, using 'Merck Silica Gel F-254' and hexane, revealed the presence of two major bands; band I (R_F 0.40) and band II (R_F 0.65, corresponding to starting material). The mass spectrum of band I (Fig. 1) indicated molecular ions corresponding to di, tri, tetra, penta and hexachlorobiphenyls. Gas liquid chromatography (GLC) of bands I and II revealed eight and three major peaks respectively. Retention times and mass spectra data for all peak components are reported in Table 1. When irradiation was carried out in methanol, similar results were obtained, but in addition a third and more polar band appeared, containing oxygenated polychlorinated compounds with structures which have not been investigated further.

Two conclusions can be drawn from the results of this study: (i) during photolysis, chlorine is removed rather readily from hexachlorobiphenyl yielding compounds of lower chlorine content; (ii) photochemical production of new compounds formed by loss of chlorine, rearrangement or condensation may lead to further complications in residue analysis with the possible appearance of chlorobiphenyls ("peaks") in environmental samples that are not present in commercial PCB mixtures.

Selection for Resistance to Carbamate and Organophosphorus Insecticides in *Anopheles albimanus*

THE development of resistance in anopheline mosquitoes to DDT, HCH, and cyclodienes, and the consequent set back in malaria eradication programmes has lent urgency to the search for alternative insecticides to replace the chlorinated hydrocarbons. During the past few years, more than 1,300 new insecticides, chiefly organophosphates and carbamates, have been tested under an international collaborative programme of the World Health Organization[1]. Testing consists of seven sequential stages and only insecticides that satisfy the criteria in all stages are recommended for use on a large scale.

One of the insecticides that satisfied the criteria of stage VI (operational evaluation) and has been found suitable for stage VII (epidemiological evaluation) is the carbamate, propoxur[2]. It is intrinsically more toxic to adults of many mosquito species than dieldrin, malathion, fenthion and fenitrothion, and as a residual spray has been found to be effective for 2 to 4 months against *Anopheles gambiae* and *A. funestus* in Africa, *A. stephensi* and *A. dthali* in Iran, and *A. albimanus* in El Salvador[2].

No case of resistance to carbamate or organophosphorus insecticides has yet been reported although tolerance to malathion has been suspected in *A. albimanus* in Guatemala and Nicaragua[3,4] and subsequently demonstrated in El Salvador[16]. In this communication we report the development of high degrees of carbamate and organophosphorus resistance in *A. albimanus* resulting from intensive selection pressure in the field, and subsequently in the laboratory.

Earlier attempts to induce carbamate resistance in *A. albimanus* by laboratory selection have been unsuccessful, although in *Culex pipiens fatigans* a 30× level of resistance to propoxur developed in larvae within twenty-five generations of selection pressure[5,6]. A strain of *A. albimanus* from Panama selected with *m*-isopropylphenyl methylcarbamate for fifty generations developed only a 2.8× increase in the LC_{50} level[7]. Another strain from Haiti, containing dieldrin-resistant individuals, when subjected to larval selection pressure by propoxur for nineteen generations and to adult pressure during the

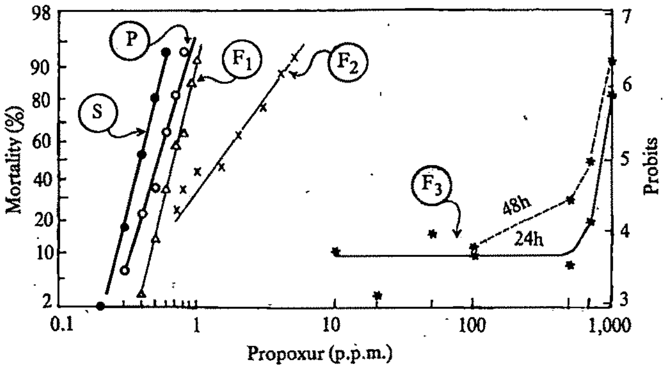

Fig. 1 Dose/mortality relationships of larvae of susceptible (S), El Salvador (P) and propoxur-selected (F_1, F_2, and F_3) populations of *Anopheles albimanus*.

subsequent fourteen generations, exhibited only a 3 × increase in larval LC_{50} and 3.5 × increase in adult LC_{50} (ref. 4).

We recently studied populations of this mosquito from El Salvador, where it is resistant to both DDT and dieldrin[3,8,9] and has also been exposed to parathion, methyl parathion, malathion, trichlorfon, thiometon, 'Azodrin' (3-hydroxy-*N*-methyl-*cis*-crotonamide dimethyl phosphate), and DDT. In El Salvador and elsewhere in Central America, *A. albimanus* is often found breeding in or near cotton fields[10] which are heavily treated with these insecticides. As many as thirty applications of insecticides during the 6 month cotton growing season are not unusual (unpublished information from various sources including the El Salvador Department of Agriculture).

Eggs were obtained from adults collected on June 16, 1970, at Hacienda Melara, Department of La Libertad, El Salvador (given by Dr S. G. Breeland) and a vigorous colony was established in our laboratory. The larvae were fed on a mixture of Purina laboratory chow and yeast and the colony was maintained in controlled conditions of 26°–27° C and 60% relative humidity. The adults were fed on rabbits at the initial stages of this work and later on white mice. Larval and adult susceptibility tests were carried out as previously described[11]. In the adult tests glass-fibre filter paper was substituted for cellulose paper as the latter is known to reduce variability with carbamates[12]. The larval LC_{50} values obtained (Table 1) indicate increases in tolerance to propoxur, carbaryl, malathion, parathion and methyl parathion in the range of 1.1 × to 3.4 × compared with a mixed susceptible strain of Haiti/Panama origin.

When we subjected the El Salvador strain to larval selection pressure by propoxur at the 90–95% level of mortality, the larval LC_{50} rose only gradually at first, that is, from the parental 0.53 p.p.m. to 0.68 p.p.m. in the F_1 generation, and to 1.5 p.p.m. in the F_2 (Fig. 1). A change in slope of the dosage-mortality line of the F_2 generation from 3.3 in P_1 to 1.4 was more indicative of impending resistance. Selection for a third generation resulted in a marked increase in resistance to propoxur. Concentrations of 10–500 p.p.m. produced 24 h mortalities of from 3 to 15%; 1,000 p.p.m. resulted in only 81% mortality. If, at the end of the 24 h exposure, the larvae were held in clean water for an additional 24 h, only slight evidence of delayed mortality was observed. In these conditions, concentrations of 100, 500, 700 and 1,000 p.p.m. produced 11, 28, 48 and 91% mortality, respectively (Fig. 1).

Table 1 Response to Various Insecticides in Susceptible, Parental, and Propoxur-selected Strains of *Anopheles albimanus*

	24 h LC_{50} (p.p.m.)

$$\text{* Resistance ratio} = \frac{LC_{50}\ P_1 \text{ or } F_{3+1} \text{ strain}}{LC_{50} \text{ susceptible strain}}$$

† LC_{50} of susceptible Gorgas strain.

To characterize the cross-resistance pattern of the strain, susceptibility tests were carried out on an unselected generation derived from the F_3, referred to as F_{3+1}. There was no detectable difference in susceptibility of F_3 and F_{3+1} larvae to propoxur. The tests indicated that resistance extends also to the carbamate carbaryl at a very high level (74.8 ×), and further it involves several organophosphorus insecticides, namely parathion (35.5 ×), methyl parathion (36.9 ×), malathion (20 ×), and fenitrothion (9.6 ×) (see Table 1). A lower level of resistance to paraoxon (approximately 5 ×) was found, and little or no resistance to dichlorvos and fenthion. The above levels of resistance are interesting because they appear to be approximately proportional to the pre-selection levels found in the parental field strain. Laboratory selection by propoxur therefore had the effect of magnifying the low levels of organophosphorus resistance which existed in the field population. Selection also increased the level of DDT resistance from the initial 4.6 × to 20 ×, but had no effect on dieldrin resistance.

Until biochemical tests are completed we cannot know the precise mechanisms responsible for this resistance. Evidence for physiological resistance, however, is readily apparent in the results so far obtained with synergists. The effects of piperonyl butoxide, triphenyl phosphate (TPP), S,S,S,-tributyl phosphorotrithioate (TBPT), and 1,1-*bis*-(*p*-chlorophenyl) ethanol (DMC) were studied by pretreating the resistant larvae with a sublethal dose of synergist 4 h before treatment with the insecticide (Table 2). Synergists were used at 10 p.p.m. except for TBPT which was used at 20 p.p.m. Piperonyl butoxide caused no increase in mortality with 100 p.p.m. propoxur, but with 500 and 700 p.p.m. it produced a marked increase. The absence of synergism at 100 p.p.m. of propoxur indicates that at this dosage a sufficient amount of detoxication enzyme remained uninhibited and was able to cope with the insecticide. At doses of 700 p.p.m. and above, however, the detoxication capacity of larvae was rapidly depleted. In contrast, carbaryl synergism occurs at lower dosages of insecticide. Synergism of carbamates by piperonyl butoxide suggests that microsomal mixed function oxidases are involved in resistance[13]. Further evidence of this is the effect of piperonyl butoxide on the toxicity of the phosphorothioates parathion, methyl parathion, fenitrothion, and fenthion. As expected, a strong degree of antagonism towards these was observed, indicating the inhibition of oxidative enzymes involved in the P=S to P=O activation step. With the phosphates dichlorvos and paraoxon no detectable effect was noted (Table 2). Because of the high degree of resistance to parathion (35.5 ×), some synergism of paraoxon might also be expected. That none was observed indicates that resistance involves an attack on the thionate before its conversion to the phosphate and/or non-oxidative degradation of the phosphate. In this respect, the low level of synergism obtained on paraoxon by TBPT, an inhibitor of desethylation[14], may be significant. The synergism of malathion by TPP would also suggest the presence of carboxyesterase detoxication enzymes[15].

A limited number of tests on adults revealed that resistance to propoxur is considerably lower in this stage than in larvae. The LC_{50} value of the parental adults (0.47 µg/cm²) rose only 4.3 × in the F_{3+1} generation (2.04 µg/cm²). It is therefore likely that selection for reduced cuticular penetration may also account for a portion of the observed resistance in larvae.

We expect that studies in progress in this laboratory will provide the necessary qualitative and quantitative information on the nature of the resistance factors involved. We believe, however, that the information so far obtained on resistance to propoxur and cross-resistance to fenitrothion is of major importance in mosquito control and in malaria eradication strategies in particular, since both compounds are considered as front line substitutes against DDT and dieldrin resistant anophelines.

Acceptability of Daily *l*-Tetramisole by Pound Dogs infected with *Dirofilaria immitis*

THIENPONT *et al.*[1] reported on the anti-helminthic potency of a new synthetic drug named tetramisole which, when given in a single dose, was effective against many of the intestinal and pulmonary nematodes of fourteen mammalian species. In the absence of any information on the host's reaction to tetramisole given for 30 to 40 days, an experiment was designed with the primary objective of testing the acceptance of daily doses of the drug by dogs from pounds. A secondary objective was to detect any therapeutic activity against adult *Dirofilaria immitis*.

Three pound dogs, weighing 40–50 pounds and aged 1–2 yr, were used. Each had a *D. immitis* microfilaraemia, with pretreatment concentrations of (*A*) 83, (*B*) 105 and (*C*) 5 microfilariae/20 mm^3 of blood respectively. Each was given one 50 mg tablet of tetramisole, directly or in a meatball, daily from Monday to Friday for 3 weeks, after which the dose was increased to one 100 mg tablet for the next 3 weeks. Four days after the last 100 mg dose, each dog was given a single dose at the rate of 9 mg per pound body weight.

The dogs were killed by intravenous injection of barbiturates 16 days after the last administration of drug and body cavities and viscera examined for worms. The great vessel leading to the heart was clamped off and the heart and lungs removed as a block. All chambers of the heart, the pulmonary artery, as well as all the dissectible branches of the arterial tree were opened in the search for adult heartworms. A gross examination for pathological changes was performed on all organs and principal tissues.

There were no unusual problems of drug acceptability with any of the three tetramisole regimens used. Dead worms were found in all dogs, often in the second order pulmonary arteries. All worms removed were placed in tissue culture fluid so that any movement could be observed, but none was seen. The microfilariae concentrations just before necropsy were: (*A*) 29; (*B*) 0; and (*C*) 0/20 m^3 of blood.

In the conditions of this limited experiment, there is clear evidence that tetramisole can be given to pound dogs at low concentrations for extended periods. Indications against the therapeutic use of tetramisole as a microfilaricide and as an adulticide were not observed clinically. More study is needed to determine the minimum effective concentration of tetramisole to destroy both microfilariae and adults of *D. immitis*.

Rational Design of Degradable Insecticides

I HAVE used a sterically based hypothesis of the mode of action of aryl insecticides, including DDT[1], to predict possible structures of new compounds, the synthesis[2] of which has been directed at finding insecticides with low mammalian toxicity and which, because of their inherent chemical instability, would readily degrade. Insecticidal activity has been studied

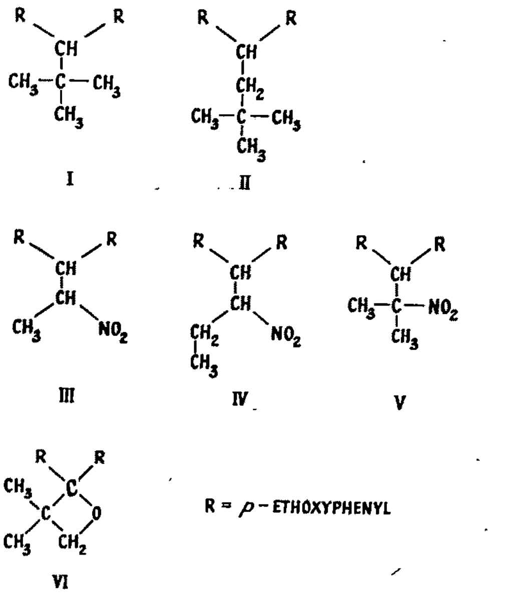

Fig. 1 Three series of non-halogenated insecticides designed from a theoretical model. In the nitroalkane and oxetane series the compounds containing two or at least one *p*-ethoxyphenyl-substituent exhibit a higher insecticidal activity than their *p*-chlorophenyl-analogues.

in susceptible and resistant housefly and investigations have been made of acute mammalian toxicity and chemical *in vitro* degradation.

The model consists essentially of a size limited "molecular wedge" which relates the physiological properties of the insecticides to their ability to keep the channel of Na^+ ions open[3] during an action potential pulse in a nerve membrane. The broad base of the "wedge" (for example, the *p*-chlorophenyl rings of DDT) was assumed to lock the whole structure by charge transfer complex formation into the protein matrix of the nerve membrane. This usually requires two phenyl rings substituted with electron donor groups. Chlorine atoms in active structures are not essential, as demonstrated by the activity of several series of new insecticides (Fig. 1 and Table 1) which do not contain halogens. These were tested for insecticidal activity in a DDT susceptible strain of housefly (WHO/IN/*Musca d.*/1) by the method described before.

An alternative to chlorine substitution in the phenyl rings comprising the base of the "wedge" was found in alkoxyphenyl derivatives. The *p*-ethoxy substituent, for example, has optimum electron donating properties within the model size limitation. Using this group the investigation of new structures centred on the design of the apex of the "wedge". In the original hypothesis, the chemical structure of the apex was only relevant with respect to size and chemical stability, and on this principle three types of compounds, branched hydrocarbons, nitroalkanes and dimethyl oxetanes, were selected and prepared (Fig. 1). The three series illustrate the importance of relating the size of the group at the apex to constructed steric three dimensional atomic models. We propose that the limit of the projected maximum van der Waals diameter (0.6 nm ±0.05) of this group determines the activity or inactivity of the compounds. In neopentane I (Fig. 1, Table 1) which is related to the less active dimethoxy analogue XV (Table 1)[4,5], the shift of the *t*-butyl group in its homologue, the neohexane II (Fig. 1, Table 1), does not alter its downward projection and the same insecticidal activity is retained.

The three nitroalkanes III, IV and V (Fig. 1) also demonstrate the importance of the design. The *p*-chlorophenyl analogues of the first two are insecticides, 'Prolan' and 'Bulan'[6], and the inactivity of 1-*o*-ethoxyphenyl-1-*p*-ethoxyphenyl-2-nitropropane[7], can be explained by its wrong dimensional fit into the described model, which suggested the high activity of the *bis*-*p*-ethoxyphenyl-compounds and the activity of the previously unknown nitroalkane isomer V (Fig. 1, Table 1). The best illustration of this design, however, is in the oxetane series VI–X (Table 1). The oxetane heterocyclic ring was selected on the basis of the construction of three dimensional atomic models and the projections of the groups. Fig. 2 shows the effect of the change of conformation of the methyl groups on the oxetanes from the 3,3-dimethyloxetane VII

* 'Sesamex' 1% solution, 0.5 ul. added with each dose of insecticide.

† Toxicity test using 2 : 1 'Sesamex' to insecticide ratio.

(Table 1) to the *trans*-3,4-dimethyl- VIII, or 3,3,4-trimethyl oxetane, XII which alters the downward projection and the diameter of the end group. According to the theoretical model the projected maximum diameter of the last two derivatives is too large and the compounds are inactive. The dimensionally correct structures are highly active insecticides. The potentiated 1,1-*bis*-*p*-ethoxyphenyl derivative VI (Table 1) was twenty-five times as active as DDT against the housefly.

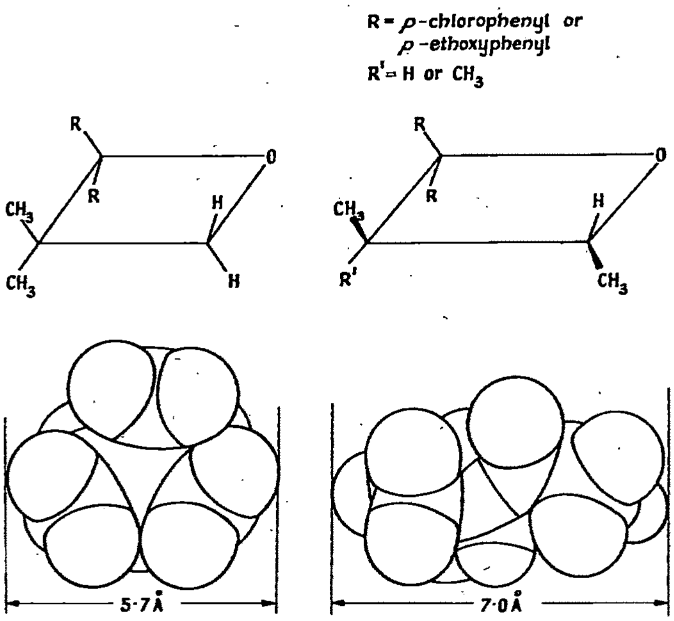

Fig. 2 The effect of conformation on activity of 2,2-*bis*-phenyl-dimethyl oxetane insecticides. The downward projection of steric atomic models with phenyl rings removed shows the change in diameter (in Ångstrom units) of the end groups for the insecticidally active 3,3-dimethyl oxetanes and inactive 3,3,4-trimethyl or *trans*-3,4-dimethyl oxetanes.

A major degradative mechanism of organic insecticides in insects and mammals is the action of microsomal mixed function oxidase[8,9]. The susceptibility of the new alkoxyphenyl structures to such attack was predicted from their chemical properties, and demonstrated by the strong potentiation of activity (Table 1), even in susceptible houseflies, by inhibitors of this enzyme system[10]. Potentiation was tested by applying 0.5 µl. of a 1% solution of 'Sesamex' (2-(3,4-methylenedioxyphenoxy)-3,6,9-trioxaundecane) in acetone immediately after each dose of insecticide applied to the dorsum of the thorax of the housefly.

The ethoxyphenyl neopentane I (Fig. 3) is readily oxidized *in vitro* at the benzylic carbon and the neopentyl carbonium ion Ib formed from the labile 1-carbinol Ia rearranges spontaneously by the illustrated mechanism to a single product, the biologically inactive olefin Id. When R was phenyl or *p*-chlorophenyl, small amounts of olefin Ic were also isolated. Similar degradation should take place in the case of the related neohexane homologue II (Fig. 1). The major modes of biological degradation may parallel these *in vitro* transformations, and this is supported by the finding[8,11] that microsomal oxidation converts DDT by hydroxylation at the benzylic carbon to 1,1-*bis*-*p*-chlorophenyl-2,2,2-trichloroethanol. This metabolite, however, in contrast to carbinol Ia (Fig. 3), is stable.

In vitro degradation of all the insecticidal 2,2-dimethyl oxetanes VI, VII, IX, X, and XI (Table 1) was a major factor in their selection for synthesis, which takes place spontaneously (Fig. 3), yielding the inactive 1,1-diaryl-2,2-dimethylethylene and formaldehyde, and can be controlled by the addition or removal of free radical initiators[12]. When adsorbed on non-biological surfaces the oxetanes degrade rapidly. A sample of 1,1-*bis*-(*p*-chlorophenyl)-2,2-dimethyl ethylene cochromatographed with the 1,1-*bis*-(*p*-chlorophenyl)-3,3-dimethyl oxetane VII, on a deactivated preparative TLC silica gel plate using benzene as the eluent giving bands with Rfs 0.18 and 0.42 respectively. When extracted after 24 h exposure, both bands yielded only the 1,1-*bis*-(*p*-chlorophenyl) dimethyl ethylene. This rapid surface degradation of the oxetane insecticides contrasts with their stability in tests on solid samples or solutions of the compounds lasting several months, disproving the reported[13] inherent instability of some 3,3-diaryl oxetanes which could not be isolated but only detected spectrometrically in solution.

Acute mammalian toxicity was tested for several new compounds in each series (Table 1) using Swiss albino female mice of average weight 20 g. Compounds were administered intraperitoneally in olive oil and toxic effects were observed for 5 days. Five animals were used per concentration and the median lethal dose for each compound was calculated. The last column of Table 1 shows the ratios of mammalian to insecticidal toxicity in identical units (mg/kg; tested average 50 flies/gm). Even though the compounds were applied in different ways—some by topical application, others by intraperitoneal injection—a comparison of the values for the two species demonstrates an approximate fifty-fold safety margin in the acute toxicity in favour of the mammals, which is constant for different structures. The ratio of toxicities using the alkoxyphenyl nitrobutane IV (Table 1) with added

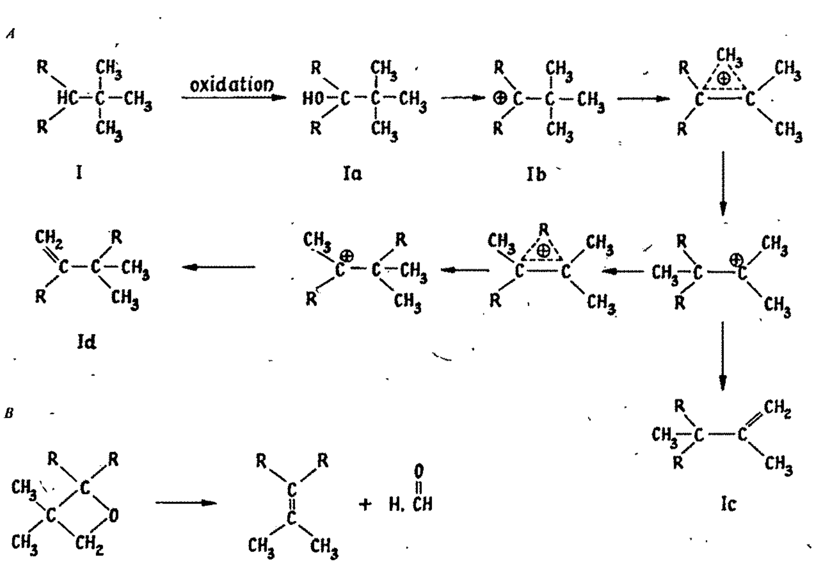

Fig. 3 Chemical degradation in two series of the new insecticides. *A*, The phenyl neopentyl structures are degraded to inactive olefins Ic and Id after hydroxylation to carbinol Ia. This rearrangement takes place at room temperature in the presence of even weak Lewis acids such as LiCl. *B*, The dimethyl oxetanes are degraded spontaneously when adsorbed on surfaces to formaldehyde and inactive 1,1-diaryl-2,2-dimethyl ethylenes. This degradation can be controlled by the addition of free radical initiators. All degradation products were identified by proton NMR, mass spectra and elemental analyses.

synergist demonstrates the selectivity of the synergist to insects and also the advantage of the potentiation in improving mammalian-insect toxicity ratio. For DDT XVII (Table 1) the ratio cannot be increased as its insecticidal activity cannot be potentiated. Although tests were carried out on only two species it is reasonable to conclude that for these compounds there is no intrinsic acute mammalian toxicity inherent in the chlorine substitution and that toxicity is potentiated by microsomal oxidation inhibitors predominantly in the insect.

Table 2 Mortality Data for DDT Resistant Strains of Housefly

Numbers from Table 1 of 1,1-*bis*-(*p*-ethoxy)- or (*p*-chlorophenyl)-compounds	Turramurra *	WHT (P) †	Housefly strain and LD_{50} values (μg/insect) F_3	F_{10}	F_{41}	F_{56}	DDT F_{37}
I -2,2-dimethylpropane	3.2	3.3	3.6	4.7	>200		
I+'Sesamex'	0.32 (0.1%)				4.2 (0.1%)		
III -2-nitropropane	0.80	0.32	0.86	2.74	—	0.33

* Activity of compounds against a DDT resistant strain kept under DDT pressure and † against a field strain resistant to DDT, selected with compounds I, III and DDT for F number of generations. The selection with each compound was carried out on approximately 2,000 flies at 75% mortality level for each generation. Values in brackets are solution concentrations of 'Sesamex' synergist applied with each dose of the insecticide. All test values are for female flies. Mortality data were determined 48 h after topical application of insecticide and synergist in an acetone solution to two day old female flies fed on sugar only diet. Mortalities were compared with zero mortality in identically treated controls.

The decrease in the degree of oxidative degradation of *p*-chlorophenyl analogues such as DDT (revealed comparing the synergism of oxetanes VII and VI of Table 1) probably accounts for their persistence and that of their metabolites in the environment.

The most important factor which would account for the general low mammalian toxicity of this type of insecticide is the negative coefficient of insect mortality to temperature, which was also demonstrated for the new structures[14]. In warm blooded animals this effect would decrease the "locking" of the aryl structures into nerve membranes and diminish the nerve ion-flux disturbances attributed to this action.

The genetically developed enzyme DDT-dehydrochlorinase, which is a major factor in the build-up of resistance[15] to insecticides containing the 2,2,2-trichloroethane structural group, obviously cannot affect the nonhalogenated compounds listed in Table 1. The new insecticides had high activity against a field strain of the housefly resistant to DDT (Table 2). In a laboratory study using the 1,1-*bis*-(*p*-ethoxyphenyl)-2,2-dimethylpropane I and 2-nitropropane analogue III (Table 2) the parent generation (WHT-P) was a heterozygous field strain of the housefly with considerable resistance to DDT. For the three compounds tested in each generation approximately 2,000 flies were selected at a 75% level. A sample of female flies was then treated and the mortalities were counted 48 h later. The parent strain rapidly developed a complete resistance to DDT; resistance to the dimethylpropane I developed more slowly, while the nitropropane III gave inconsistent results and the initially developed resistance could not be maintained. Although the use of the 'Sesamex' synergist controlled the resistance to the new compounds, additional modes of resistance to DDT-type insecticides are now recognized[16] and further studies are required to determine their development by selection with the listed compounds.

Although positive results were obtained in the rational design of insecticides the question remains whether higher mammalian safety margins, non-halogenated, degradable structures and activity against resistant pests, outweigh the economic disadvantages of the compounds. Beneficial properties are sometimes coupled with decreased persistence and need for potentiation which may make the new compounds unacceptable under present agricultural and public-health practice of pest control.

Mammalian toxicity tests were carried out in part at the Department of Pharmacology, University of Melbourne, and the Commonwealth Serum Laboratories, Melbourne. I thank Dr E. Shipp for supervising the entomological tests and Mr R. Eibl for technical assistance.

Photomimetic Effect of Acetylcholine on Morphogenesis in *Trichoderma*

BIETH *et al.*[1] have demonstrated that synthetic photochromic agents can effect control of acetylcholinesterase activity *in vitro*, and suggest that photomorphogenetic processes are mediated by similar systems. Jaffe[2] has shown that acetylcholine mimics red light in some plant photomorphogenetic processes in which phytochrome is considered to be the photoacceptor. He also found increased efflux of acetylcholine from roots following red light treatment.

Various fungi have a photomorphogenetic pigment system which differs from the phytochrome system of higher plants insofar as the photoacceptor absorbs blue instead of red light[3,4].

Sporulation (conidiation) is induced at the growing edge of 1 day old cultures of the imperfect fungus *Trichoderma viride* Pers. ex Fries by minuscule quantities of blue light; the half maximum response is reached with 6.6×10^{-10} Einsteins/cm^2 at 447 nm[3]. Evidence with inhibitors suggests a requirement for nucleic acid synthesis for morphogenesis as sporulation can be selectively suppressed by some base analogues while only slightly affecting growth[5].

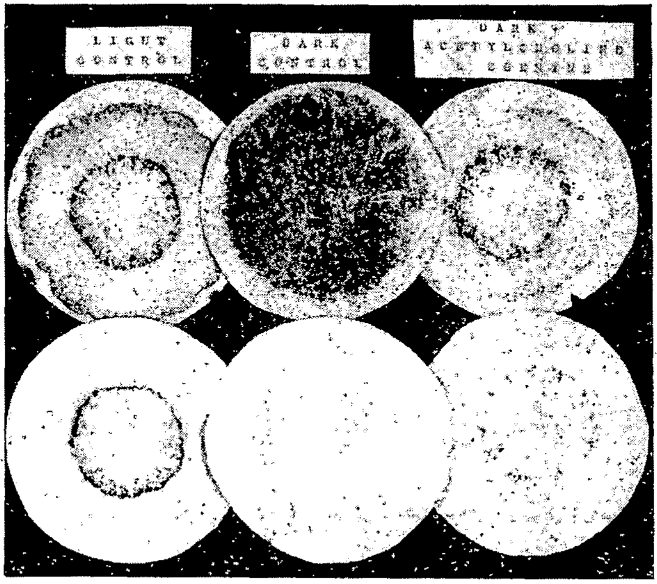

Fig. 1 Dark induction of sporulation (conidiation) in *Trichoderma* by acetylcholine and eserine. An agar block with mycelium of *Trichoderma viride* Pers. ex Fries was cultured for 34 h on one circle of Whatman No. 50 hardened filter paper, soaked with 2.3 ml. of double strength Difco potato dextrose broth, in sterile conditions at 24° C. The filter paper circles were then transferred to a second dish containing a 7 cm circle of Whatman No. 1 filter paper, soaked with 1.0 ml. of the above medium with or without the addition of 10^{-4} M acetylcholine (BDH) and 5×10^{-6} M eserine (Calbiochem) final concentrations. The light controls were then illuminated for 3 min with fluorescent lights. All other culturing procedures were performed with a red safelight. Bottom row: fixed in 80% ethanol 32 h after transferring; top row: fixed as above, dried and then stained with cotton blue to show mycelia as well as spores.

We wished to ascertain whether the blue light-induced morphogenetic response could be mediated through an acetylcholine type response, in a similar manner as that of the higher systems.

Agar blocks of plant fungal mycelium were planted on filter paper soaked with medium and cultured for 30–34 h. The filter papers were then transferred to Petri dishes containing fresh media with the experimental additives. Control cultures were illuminated for 3 min to induce sporulation. Detailed methods are described in ref. 5.

Preliminary experiments showed that acetylcholine alone could not induce sporulation in the dark under a wide range of concentrations (10^{-5} to 10^{-1} M). In the presence of the acetylcholinesterase inhibitor eserine (physostigmine) it was possible to induce sporulation, mimicing photoinduction in conditions which slightly inhibited growth (Fig. 1). Harsh physical and nutritional conditions such as desiccation or temporary starvation can induce a diffuse sporulation quite different from the distinct ring of spores induced by light or by acetylcholine. The acetylcholine antagonist curare suppressed light-induced sporulation, as would be expected from our preliminary findings, but it inhibited growth as well.

The ranges of effective acetylcholine and eserine concentrations inducing sporulation were found to be narrow (Fig. 2).

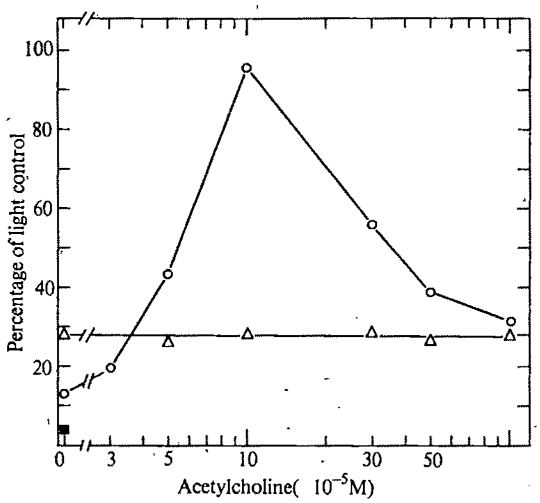

Fig. 2 Effect of acetylcholine and eserine concentrations on dark sporulation of *Trichoderma*. The experiments were performed as in Fig. 1. After ethanol fixation and drying, the spores were washed off in distilled water with a rubber policeman and counted microscopically in a Levy–Hausser corpuscle counting chamber. About 3×10^3 spores were contained in a light control spore ring. Results with 10^{-5} M eserine were similar to those with 3×10^{-6} M eserine shown above. ○, 5×10^{-6} M eserine; △, 3×10^{-6} eserine; ■, dark control.

Higher plants contain a blue light absorbing photomorphogenetic pigment system as well as the red light absorbing phytochrome. This blue light system has a similar action spectrum to that of *Trichoderma*. In some plants the direction of morphogenesis is sometimes controlled by an interplay of the two pigment systems[6]. If both systems act through acetylcholine some rethinking of the modes of action of each system will be necessary.

We thank Dr Israel Silman for useful discussion, and Dr M. J. Jaffe for access to an unpublished manuscript. We also thank Miss Tami Shihi for technical assistance. This research was supported in part by a grant from the US Department of Agriculture.

Proof of Two Distinct Enhancement Effects by Blue Light on Oxygen Uptake in *Chlorella*

MANY authors have reported an enhancement of oxygen uptake in *Chlorella* by blue light[1-4]. The pigment responsible has not been definitely established, but may well be a flavin[5]. The mechanism of the enhanced oxygen uptake is also uncertain.

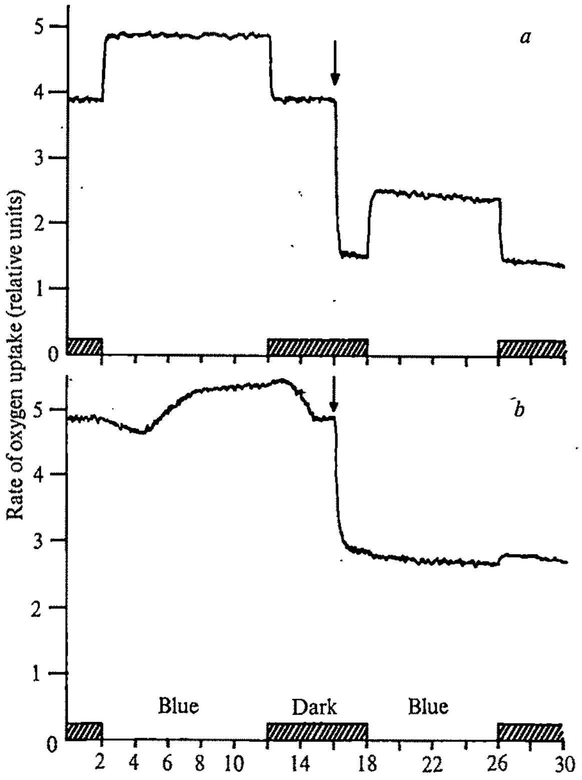

Fig. 1 The effect of blue light and cyanide poisoning on the respiration rate of two *Chlorella* strains. *a*, Colourless *Chlorella* mutant "G-27" in the presence of 3×10^{-5} M FMN (the curve has been corrected for uptake due to the auto-oxidation of FMN[9]; *b*, *C. pyrenoidosa* chick treated with 5×10^{-6} M DCMU. Cyanide (final concentration 2×10^{-4} M) was added to the preparations at the time indicated by the arrows. The enhancement was stopped in *b*, but not in *a* (pH=6.6 in all cases). Note the immediate onset of the enhancement in *a*, in contrast to *b*.

The enhanced respiratory activity has a respiratory quotient (RQ) of 1, and the same temperature dependence as dark respiration[5,6]; the cyanide sensitivities of the light stimulated oxygen uptake and of that part of glucose (dark) respiration which is inhibited by cyanide are identical[5]. It has been suggested[5,6] that the effect is due to a stimulation of normal respiratory pathways, possibly caused by an increased level of substrate (for example, a release of stored carbohydrate). Laudenbach and Pirson[7] investigated the effect of red and blue light on the carbohydrate content of the cells, and concluded that the effects of light on respiration are secondary and that a more direct effect might be a change in permeability of the plastid membrane.

On the other hand, Schmid and Schwarze[4] have reported oxygen uptake enhanced by blue light in a colourless *Chlorella* mutant, which they attribute to an FMN-dependent amino-acid oxidase. Crude enzyme extracts of this oxidase showed enhanced oxygen uptake in blue light, implying that blue light acts directly to increase oxygen uptake. With this amino-acid oxidase Schmid and Schwarze could account for the fact (reported in most of the above mentioned publications) that starvation of the cells for many hours before illumination gave an increased blue effect. They reasoned that in starvation the cells start hydrolysing their own protein, giving a higher concentration of free amino-acids available for direct oxidation. The authors assumed the enhancement effect observed in their mutant was the same as that reported by other groups, although one would not expect an RQ of 1 for protein oxidation. No inhibitor, temperature dependence or other studies were reported. We have found a second *C. pyrenoidosa* mutant ("G-27", described by Bendix and Allan[8]) with this FMN-dependent amino-acid oxidase activity[9].

Table 1 Distinguishing Features of the Two Types of Blue Light-stimulated Oxygen Uptake in *Chlorella*

Enhancement effect	Type I	Type II
Time of appearance	Delayed 6–10 min	Within 5 s
Cyanide sensitivity	97% inhibited at concentration of 2×10^{-4} M (ref. 5)	Unaffected by concentration of 2×10^{-2} M
Respiratory quotient	1	?
Pigment responsible	Possibly FMN	Probably FMN[9]
Probable mechanism	Stimulation of normal endogenous respiration and electron transport chain	FMN-dependent amino-acid oxidase
References cited	1–7	4, 9

We have now shown that this blue light phenomenon is different from that found in the normal (photosynthetic) *Chlorella* strain (Fig. 1). In the light of this we re-examined other reports of blue light enhancement effects in *Chlorella* and found that both effects had been observed, but not distinguished. We therefore wish to alert other investigators to this possible pitfall. Two easily checked, distinguishing features are the time course of the effects and their cyanide sensitivities. In DCMU-treated cells of the normal, photosynthetic strain, blue light causes an initial inhibition of oxygen uptake, which is followed 6–10 min later by an enhancement. This enhancement is virtually eliminated by 2×10^{-4} M cyanide (Fig. 1*b*), and is the same effect reported by Ried and further described by Pickett. The blue light-enhanced oxygen uptake in the "G-27" mutant, however, appears within 5 s (Fig. 1*a*) and is not inhibited even by 2×10^{-2} M cyanide.

For ease of identification we suggest the delayed, cyanide-sensitive effect be labelled "type I" and the immediate, cyanide-insensitive effect "type II". The properties of each are summarized in Table 1, together with the cited references allocated according to which effect they seem to describe. In the future authors should make clear which effect is being studied.

Possible Ball Court at La Venta, Mexico

LA VENTA, one of the earliest Olmec sites, is located on an island in the Tonala River which forms the boundary between the Mexican states of Veracruz and Tabasco (18° 10′ N, 94° 5′ W). The site is believed to have been built and maintained during the period from 1000 BC to 600 BC or even later[1], primarily as a ceremonial or religious enclave[2]. For years, no ball court, usually an important feature of sacred Mesoamerican precincts, had been found at La Venta[3].

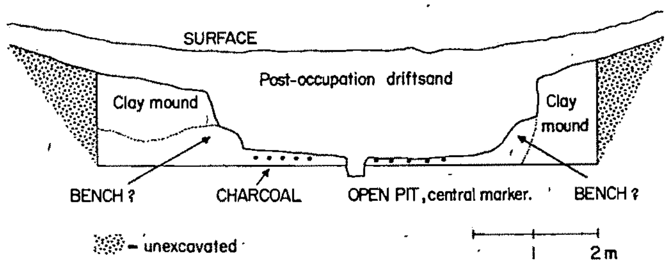

Fig. 1 Cross section through suspected ball court at La Venta, Mexico.

By 1963, at least 267 ball courts had been identified in Mesoamerica[4]. The Mesoamerican ball game is said to have originated in the La Venta culture and to have spread to the Maya and other Mesoamerican cultures[5]. An early stela found on the Veracruz Gulf Coast (the Matisse stela) depicts what is thought to be a ball player with hands upraised in front of his face[6]. Monument thirty-four at San Lorenzo, another Olmec site, also probably represents a ball player[7], while the helmeted colossal Olmec stone heads possibly represent champions of the ball game[8]. At San Lorenzo, ball player figurines have been found in the levels of the San Lorenzo phase which has been placed by radiocarbon dating to a range from 1150 to 900 BC (private communication from M. Coe). It has even been suggested that the ball court heroes were all politicians[9].

A structural complex recently discovered at La Venta, which may be a ball court, consists of two parallel mounds at the southern end of the "Stirling group", each about 14 m wide. That on the west is 55 m long and the other 39 m long[10], which suggests that the ball court was of the open ended type and thus stylistically consistent with other early courts.

A sample of charcoal from the uppermost clay construction layers of the court floor (Fig. 1) has been dated (UCLA-1630) at 2710 years (760 BC) using the newer half-life of 5,730 ± 30 yr. This radiocarbon date is consistent with various others obtained from the site[1,11–13].

The earliest court so far found in the lowland Maya area is probably that at Copan which is the earliest in a superimposed series of three courts and which possibly belongs to the Early Classic period (AD 300–600). This was a comparatively narrow open court, smoothly paved with low slanting ramps on either side and possibly with plaster markers[14,15].

UCLA–1630 seems to be the first radiocarbon date for a ball court, previous dating having been based on methods of varying degrees of accuracy, from ceramic association to assessment of architectural style and hieroglyphic inscriptions[4]. Another suspected ball court of perhaps similar antiquity is that at the Olmec site of San Lorenzo, constructed of earth and clay fill and built during the Palangana phase. This phase appears to have cross-ties to Mamon and to Drucker's La Venta material which places it into the 600–400 BC range (Coe, private communication).

The date of 760 BC would make the feature at La Venta the oldest ball court in Mesoamerica. The oldest definitely identified ball court seems to be that at Monte Alban and attributed to the Monte Alban Period II, which began at about the end of the third century BC, when Maya-like features, including stelae engraved with hieroglyphics, appeared at Monte Alban[6]. The detailed features of this court are unknown, but later Alban and Zapotec ball courts are noteworthy in being fully enclosed and in having two niches in opposite diagonal interior angles of the court instead of rings or other devices[6]. The dating of Monte Alban has been subject to numerous uncertainties[16], and most recently excavations at Lambityeco, near Monte Alban, by John Paddock are said to raise implications that Monte Alban had fallen several centuries earlier than had been believed, leaving a serious gap in dating sequences[17].

Do Intracellular Concentrations of Potassium or Sodium Regulate the Strength of the Heart Beat?

CERTAIN "inotropic" responses in which the strength of the heart beat increases are accompanied by a loss of potassium from the cells and a simultaneous gain of sodium[1]. The question of immediate interest is whether these changes of cellular ion content and of contractile force—if indeed they are always thus associated—reflect a mechanism which controls the heart twitch or whether they are incidental. We have set out to re-examine this question, much debated in the past but not yet entirely resolved[2].

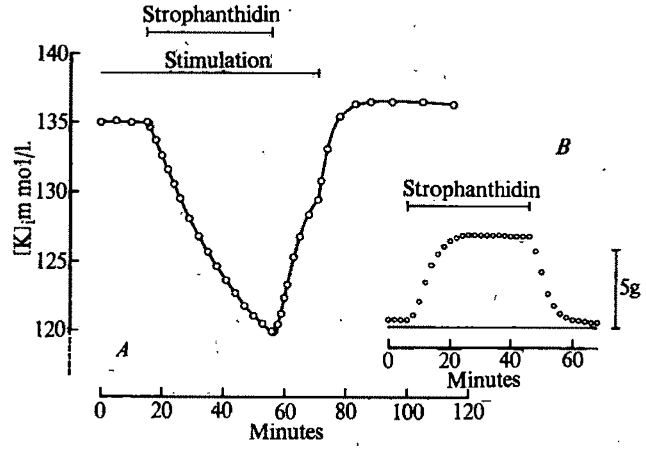

Fig. 1 Effects of 3-acetyl strophanthidin (5×10^{-7} M) on cellular potassium movements (*A*) and twitch tension (*B*). External medium: 0.5 mM $[\text{Ca}]_o$, 2 mM $[\text{K}]_o$, and isethionate substituted for chloride. *A*, Ventricle stimulated for 15 min immediately before start of the experiment, and thereafter for the time indicated by bar (rate 20 min^{-1}). Ordinate: Concentration in cell water. *B*, Peak twitch tension (plotted at 2 min intervals) developed by a ventricle stimulated (at 20 min^{-1}) throughout. (For details of technique, see ref. 14.)

Two parallel series of experiments were made to examine (i) the changes in the twitch tension developed by frog ventricles (*Rana pipiens*) during various inotropic responses, and (ii) the associated net movements of potassium between the heart and perfusion fluid (measured essentially as described in ref. 3, using the improved experimental procedure developed for the study of calcium fluxes[4]). We were thus able to confirm and extend some earlier results by showing that many, though not all, of the inotropic responses examined are accompanied by a net efflux of potassium ions from the heart cells, followed by a net influx during recovery from the inotropic effect. Potassium movements of this kind were quite marked during responses resulting from (i) changes in the stimulus rate ("staircase" phenomena), (ii) reduction of the external potassium concentration, $[\text{K}]_o$, and (iii) application of the cardiac steroid 3-acetyl strophanthidin (see magnitude of the potassium movements in Figs. 1, 3 and 4). Further, all these results were essentially unchanged when the normal perfusate containing 118 mM Cl was replaced by one in which chloride was substituted by larger anions such as isethionate or ethyl sulphate, which are known to penetrate the cell membrane only slowly[5,6]. While this excludes any appreciable contribution of anion movements, the possibility remains that the cation exchange, that is, cellular potassium for external sodium, is essential to the mechanism underlying the inotropic responses. Indeed, two hypotheses invoked to interpret the above and other related results are based on this idea, the earlier correlating strength of contraction with the level of potassium (refs. 1, 7, but compare 8), the later with that of sodium inside the heart cells[9]. In particular, it has been proposed[9,10], and widely accepted[11,12], that changes in cellular sodium concentration are linked with those of "activator" calcium and thus help to regulate contractile activity.

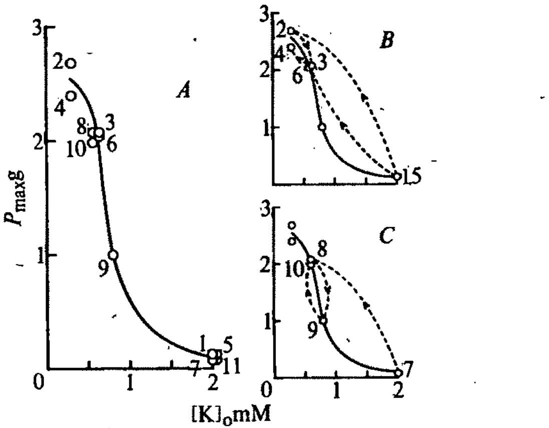

Fig. 2 Steady state twitch heights in media of different $[\text{K}]_o$. 0.5 mM $[\text{Ca}]_o$, isethionate substituted for chloride. Stimulus rate 20 min^{-1}. *A*, Dose-action curve, peak tension P_{max}, versus $[\text{K}]_o$, summarizing results of an experiment; numbers indicate sequence of changes in $[\text{K}]_o$. *B*, and *C*, Schematic representation of the different pathways (in the same experiment) leading from tension level in 2 mM $[\text{K}]_o$ to that in 0.6 mM $[\text{K}]_o$; cf. 1→2→3 and 5→6 in (B), 7→8 and 7→8→9→10 in (C). (Note also the two pathways to tension level in 0.3 mM $[\text{K}]_o$: 1→2 and 1→2→3→4 in (*B*).)

In analysing these ideas further, the subsequent experiments were made in Cl-free media, with isethionate as the substitute anion, to ensure that movements of sodium of essentially the same size, but opposite direction, accompanied the potassium movements which we determined. (Of course, the equivalence is not exact because of the movements of other ions, notably calcium. The change in the intracellular ion balance, however, as produced, for example, by the known calcium movements in similar conditions[13], is too small to affect the validity of the above assumption and of the conclusions to be derived later.)

Three sets of results emerged which are difficult to reconcile with the view that contraction is sensitive to changes in level of cell potassium or sodium. (1) During some of the inotropic responses, twitch tension and level of cellular potassium, $[\text{K}]_i$, altered with markedly differing time courses, the changes of tension being usually more rapid than those of $[\text{K}]_i$. Fig. 1 illustrates this difference by the effects obtained with a submaximal dose of acetyl strophanthidin (5×10^{-7} M; maximum twitch tension was obtained with concentrations greater than 10^{-6} M in otherwise similar experiments). Twitch tension rose to a new steady level within 15–20 min of the application of the drug (Fig. 1*B*), whereas the level of $[\text{K}]_i$ continued to decrease, though at a gradually declining rate, for much longer (> 40 min). The later part of Fig. 1 shows the recovery from the drug action: the tension declined to the original low level (Fig. 1*B*) and the tissue reabsorbed potassium after withdrawal of the drug, and subsequent cessation of stimulation (Fig. 1*A*).

Experiments in which the effects of low $[K]_0$ were examined in the same way as described for acetyl strophanthidin yielded closely similar results—a rapid increase of tension (within 10–20 min) to a steady high level, associated with a progressive loss of potassium (lasting >40 min).

(2) Steady twitch tensions recorded in a low $[K]_0$ medium were not related to intracellular potassium (or sodium) concentrations, which could be adjusted by pretreatment of the ventricles with various low potassium fluids. Fig. 2*A–C* illustrates the steady state tensions in an experiment in which a ventricle was exposed to fluids of various $[K]_0$ for 10–20 min (2 mM being the level in "normal" fluids). As is seen, twitch heights in a 0.6 mM $[K]_0$ medium were little different whether recorded after the concentration step from 2 to 0.6 mM $[K]_0$ or after the more complex sequences which included exposure of the ventricle to either 0.3 or 0.8 mM $[K]_0$. (Compare sequences 5→6 and 1→2→3, and sequences 7→8 and 7→8→9→10 in Fig. 2*B* and *C* respectively). By contrast, potassium release from the cells markedly depended on the sequence of concentration change, being, for example, 7.2 mmol/l. cell water (±0.7, s.e. of five determinations) after the change from 2 to 0.6 mM $[K]_0$, as against 16.3 mmol/l. (±1.2, s.e. of five determinations) after the change through the level of 0.3 mM $[K]_0$. (These results were obtained from ten experiments made in similar conditions to those of Fig. 2.)

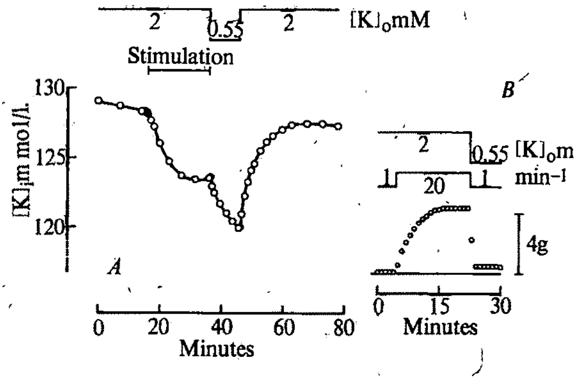

Fig. 3 "Ascending" and "descending" staircase in media of different $[K]_0$. 1.2 mM $[Ca]_0$, isethionate substituted for chloride. *A*, Cellular potassium movements associated with periods of quiescence and stimulation (rate 20 min^{-1}) in 2 mM $[K]_0$, and with a subsequent period of quiescence, first in 0.55 mM and then in 2 mM $[K]_0$. *B*, Peak tension of twitches (plotted at 1 min intervals) in response to a high stimulus rate (20 min^{-1}) in 2 mM $[K]_0$, and to a subsequent low rate (1 min^{-1}) in 0.55 mM $[K]_0$.

It should also be mentioned that pretreatment of heart cells with very low potassium fluids (<0.5 mM $[K]_0$) sometimes affected the subsequent twitch tension which, however, became weaker rather than stronger, possibly as the result of "fatigue" (compare tension levels 2 and 4 in 0.3 mM $[K]_0$ of Fig. 2, and also the results of Fig. 4*B*).

(3) Well defined conditions exist in which changes in twitch tension were associated with potassium and sodium movements in directions opposite to those predicted by any of the hypotheses outlined here. For example, the weakening of heart twitches during a period of reduced stimulus rate ("descending" staircase), which is usually associated with potassium uptake (and sodium loss), also occurred when heart cells were made to lose potassium (and gain sodium) by exposure to a low $[K]_0$ medium during this period. Indeed, the decline of twitch tension so obtained was quite similar to that of a normal "descending" staircase, except that the final steady level of tension was slightly higher in the low potassium fluid (Fig. 3*B*). The loss of potassium during this tension decline was considerable, being comparable with that associated with the build up of tension during the "ascending" staircase (compare cellular K loss during stimulation period in Fig. 3*A*) and was followed by a net gain of this ion by the cells during the final recovery period in normal $[K]_0$ medium.

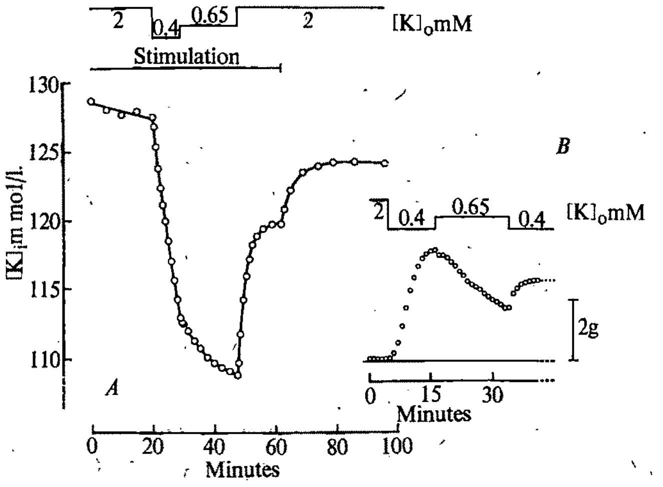

Fig. 4 Effects of several step changes of $[K]_0$ on cellular potassium movements (*A*) and twitch tension (*B*). External medium: 0.5 mM $[Ca]_0$, isethionate substituted for chloride. *A*, Ventricle stimulated as in Fig. 1. *B*, Peak tension of twitches (plotted at 1 min intervals) during continuous stimulation (rate 20 min^{-1}) in media of different $[K]_0$ as indicated. Final dotted line indicates that on return to 0.4 mM $[K]_0$ tension normally attained a plateau, though often of reduced height (compare discussion in connexion with Fig. 2).

Fig. 4 is another illustration of the concurrence of tension changes with ion movements in the "wrong" direction. Here the responses to a series of changes in $[K]_0$ were followed, first, to a step decrease, from 2 to 0.4 mM, which caused tension to rise, then to a smaller step up, from 0.4 to 0.65 mM, which caused tension to fall (Fig. 4*B*). The cellular potassium release (Fig. 4*A*) associated with the first period was in accordance with the hypotheses tested, but not its continuation during the second period, during which the direction of tension change reversed. The final sections of Fig. 4*A* and *B* show the essentially unimpaired responsiveness of the tissue to further tests, even after large and rapid losses of potassium. Thus, (*a*) potassium was taken up again after the re-establishment of normal $[K]_0$, and cessation of stimulation, respectively (Fig. 4*A*), and (*b*) the tension rose once more on again reducing $[K]_0$ (Fig. 4*B*).

In conclusion, although it is still conceivable that cellular potassium for sodium exchanges contribute in regulating the strength of the heart beat, this contribution is unlikely to be at all substantial. More probably, the principal factor common to many inotropic responses resides in the cell membrane, in as yet unknown processes which control the magnitude of cellular calcium fluxes.

Acquisition of Human Antigens by *Schistosoma mansoni* during Cultivation *in vitro*

Schistosoma mansoni may live in the portal circulation of man for many years. In the rhesus monkey, established adult worms persist even though their presence stimulates a powerful host immunity against reinfection with cercariae[1]. We have suggested that this concomitant immunity may be explained if the adult worms possess host antigens[2]; such an immunological disguise would allow these established worms to evade the efferent component of the host's immune response which kills new invading forms lacking the disguise. The existence of these host antigens at the surface of the worms has been demonstrated by transferring worms, grown to maturity in mice, directly into the portal circulation of rhesus monkeys immunized against mouse erythrocytes. Such mouse worms are rapidly destroyed by an antibody-mediated response directed against sites on the worms' surface; mouse worms survive well on transfer to normal monkeys[3].

These mouse antigens are not permanently expressed in the worm, and could no longer be detected using this system when mouse worms had been in the circulation of normal monkeys for 7 days. Nevertheless, there is good evidence that these antigens are not merely gross contaminants of host origin; they seem to be firmly bound to or incorporated into the surface membrane of the worm[3–5]. They do not seem to be mouse IgG immunoglobulin, neither are they Forsmann antigen; but they are antigenically identical to other components of the mouse erythrocyte membrane[4]. They are not present in cercariae but are partly expressed in 7 day schistosomula and fully expressed in 15 day schistosomula[5].

The origin and mode of acquisition of these antigens are unknown. We believe that they are truly of host origin and, by some means, they become incorporated into the surface structure of the schistosome. An alternative hypothesis, favoured by Capron and his colleagues[6], suggests that these antigens are synthesized by the schistosomes and mimic those of the host. It is postulated that the schistosome possesses a range of codes for these antigens and specific selection for a given mimicking antigen takes place when the worm enters a particular host.

We have recently studied the acquisition of host antigens by schistosomula during cultivation *in vitro*. Such a system is much more susceptible to detailed analysis than an *in vivo* system, and it may eventually be possible to select between the hypotheses outlined above. Because *S. mansoni* is primarily a parasite of man, and much is known of human erythrocyte antigens, we grew the schistosomes in human blood.

Schistosomula of a Puerto Rican strain of *S. mansoni*[7] were collected by allowing cercariae to penetrate specially prepared isolated mouse skin; they were then cultured *in vitro* for 15 days (J. A. C. and S. R. S., in preparation). The culture medium consisted of equal volumes of fresh human or monkey serum and Earle's balanced salt solution, lactalbumin hydrolysate at a final concentration of 0.25%, 1% washed human or monkey erythrocytes and antibiotics. The medium was gassed with 8% CO_2 in air to give a *p*H of 7.4. Incubation was at 37° C and the medium was replaced at intervals of 3–4 days, except that the original erythrocyte inoculum was retained. Two ml. of this medium, in a Leighton tube, supported the growth of 200–250 schistosomula. At 15 days, the schistosomula had shown satisfactory development according to the criteria of Clegg[8]; indeed they were more advanced than schistosomula grown *in vivo* in mice for the same period.

Meanwhile, rhesus monkeys were immunized with various types of washed human erythrocytes in Freund's complete adjuvant[3]; control monkeys were injected with adjuvant alone or not treated. Three weeks after primary immunization, the monkeys received a booster intraperitoneal injection of washed erythrocytes. One week later, the 15 day schistosomula were washed in Earle's solution containing 1% monkey serum and transferred to immunized and control monkeys by cannulation of the mesenteric veins[5]. Each monkey received a carefully counted number of schistosomula; the actual numbers transferred varied between 165 and 247 in the first experiment and 105 and 128 in the second. Four or 5 weeks after transfer, when any surviving worms would have reached maturity, the monkeys were killed and perfused and the adult worms were recovered[7].

Table 1 Acquisition of Human Host Antigens by Schistosomes *in vitro*

Monkey No.	Immunization	Erythrocytes in culture system	Worm recovery 5 weeks later (%)
601	FCA	Monkey	67
608	Nil	Monkey	79
602	FCA	AB−	73
607	Nil	AB−	45
603	Anti-AB−	Monkey	103
604	Anti-AB−	Monkey	96
605	Anti-AB−	AB−	3
606	Anti-AB−	AB−	5

FCA, immunization with Freund's complete adjuvant alone.

The human blood used in the first experiment was of type AB Rh−; control cultures were maintained in normal rhesus monkey blood. Table 1 summarizes the plan and the results of this experiment. Control monkeys accepted schistosomula grown in either human or monkey blood with equal readiness and survival rates were high. Anti-AB− monkeys accepted worms grown in monkey blood but almost completely destroyed those cultured in AB− blood. Evidently, these schistosomula had acquired human antigens during their cultivation *in vitro* and these served as targets for the immune response of the anti-human monkeys.

The second experiment was designed to determine whether blood group specific antigens were among those acquired by the schistosomula. Two bloods differing in respect of several major antigens were chosen: A, DE, N−, Fy(a+); and B, dē, N+, Fy(a−). Rhesus monkeys were immunized with one or other type of washed erythrocytes in Freund's complete adjuvant followed by a booster dose intraperitoneally; control monkeys were injected with Freund's complete adjuvant alone. Schistosomula were cultivated for 15 days in media based on these bloods and were then washed and transferred into rhesus monkeys according to the scheme shown in Table 2. Five weeks later, the surviving adult worms were recovered.

Table 2 Specific Blood Group Substances as Host Antigens

Group	Monkey No.	Immunization	Erythrocytes in culture system	Worm recovery 5 weeks later (%)
Control	618	FCA	A+	76
	619	FCA	A+	45
	624	FCA	B−	73
	625	FCA	B−	85
Homologous	614	Anti-A+	A+	3
	615	Anti-A+	A+	3
	622	Anti-B−	B−	1
	623	Anti-B−	B−	3
Heterologous	620	Anti-A+	B−	14
	621	Anti-A+	B−	23
	616	Anti-B−	A+	3
	617	Anti-B−	A+	33

FCA, immunization with Freunds complete adjuvant alone.
Students t test was carried out after arc sin transformation of the data. Control versus homologous: $P<0.001$; control versus heterologous: $P<0.01$; homologous versus heterologous: $P<0.05$

When the transfer was homologous, "A+ worms" into anti-A+ monkeys and "B− worms" into anti-B− monkeys, almost all the schistosomula were destroyed. With heterologous transfer, "A+" worms into anti-B− monkeys and vice versa survival rates were more variable. Certainly, significantly fewer worms survived than in the control monkeys, but more survived than in the homologous transfers. We interpret this result as meaning that the schistosomula acquired, *in vitro*, antigens which were common to the two erythrocyte types but also, to some degree, specific blood group antigens.

We may conclude that the schistosomula of *S. mansoni* can acquire human antigens and that these antigens can be acquired during cultivation *in vitro*. Thus the *in vitro* system appears to offer a valid approach to further studies. Human antigens common to A+ and B− erythrocytes are acquired by schistosomula in culture and there is some evidence that blood group specific antigens are expressed as well. If this last finding can be confirmed, we believe that it supports the view that host antigens are truly of host origin and are not synthesized by the worm. We doubt that the selective synthesis of human blood group specific antigens is within the capabilities of a trematode parasite, even one as well adapted as *S. mansoni*.

We thank Mr John Harris for determining the blood group specificities and Mr Kenneth Gammage for assistance.

Biphasic and Reversible Adaptation of Goldfish to Alcohol

GOLDFISH are well suited to the study of the effects of alcohol on behaviour. The concentration of alcohol in their blood rapidly approximates the concentration of alcohol in the water in which they swim[1]. Thus the study of tolerance, for example, is not complicated by such variables as rate of alcohol absorption. We have studied certain responses of goldfish as a function of time in an alcohol solution, to learn whether tolerance to alcohol develops, and whether it persists after return to water.

Twenty-four goldfish (*Carassius auratus*), 3–5 cm long, were kept in 100 l. tanks containing tap water. At the start of each session, twelve were randomly assigned to an experimental group and twelve to a control group. The fish were transferred to smaller tanks containing 0.8% ethanol solution (experimental fish) or water (control fish), remaining in the respective solution, one fish per tank, for periods of 0.5 h to 42 h.

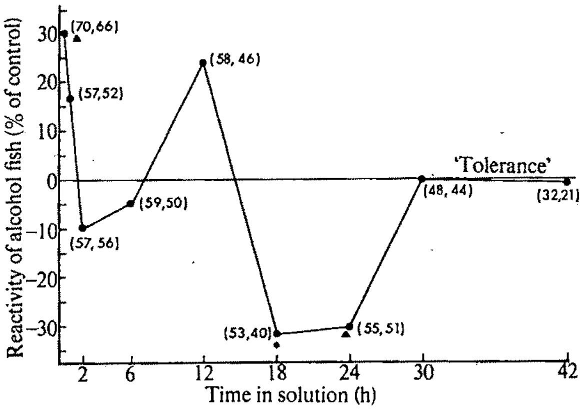

Fig. 1 Biphasic effects of alcohol on goldfish responding to an aversive stimulus after immersion in an 0.8% alcohol solution for varying periods. Each point represents the difference in the mean value of experimental fish from the mean value of concurrently run control fish, expressed as a percentage of the control value. Numbers in parenthesis represent, respectively, the experimental N and control N for each immersion period. Significant differences from control means are indicated by an asterisk ($P<0.05$) and triangle ($P<0.01$). The 12 h response was not significant ($P>0.10$).

We measured an escape reaction to an aversive stimulus. The experimental apparatus consisted of a trough 118 cm long, 3 cm wide, 4 cm deep. At one end was a "start box" 6 cm long, 3 cm wide, separated from the remainder by a trap door. A high intensity light faced the start box, opposite the trap door. For each trial a fish was placed in the start box for 30 s, the light was turned on for 3 s, and the trap door was lifted, allowing the fish to escape from the light. Response was measured as distance, in cm, the fish swam from the light in 5 s. The unresponsive fish or those that moved less than 5 cm were excluded from the analysis so that the numbers of fish in each group are unequal. Each fish was used only once so that they should not become "practised". Experimental and control fish were tested simultaneously, the trough containing the pretest-period fluid. Alcohol in water and blood was assayed by gas–liquid chromatography. Equilibration occurred within 60 min.

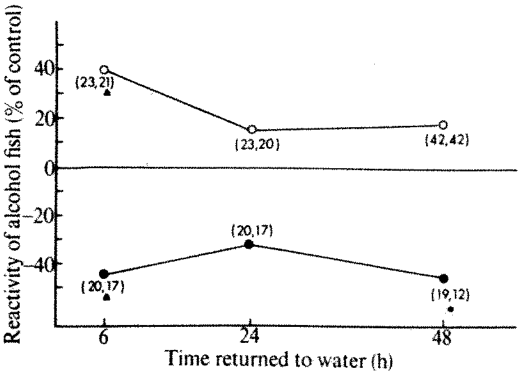

Fig. 2 Fish "tolerant" to alcohol after 42 h of immersion in an 0.8% alcohol solution returned to water for periods of 6, 24, and 48 h. Fish reimmersed in alcohol for 0.5 h continued to show an excitatory response (○). Fish immersed in alcohol for 24 h still showed a depressed response (●). Each point represents the difference in mean value of experimental fish from concurrently run control fish, expressed as a percentage of the control value. Significant differences from control means are indicated by an asterisk ($P<0.02$) and solid triangles ($P<0.01$). Numbers in parenthesis represent, respectively, the experimental N and control N.

Fish in alcohol for 0.5 h were significantly more reactive than control fish (Fig. 1). They also were more reactive after 1 h. Fish in alcohol for 2 and 6 h were a little less reactive. They were more reactive after 12 h. After 18 and 24 h, experimental fish were much less reactive. After this "depressed" phase, the groups responded similarly after 30 and 42 h of immersion.

These results indicate that during adaptation to an 0.8% alcohol solution, when the alcohol blood level rises from zero to 800 mg/100 ml. in 1 h, the goldfish pass through three phases of activity. They are hyper-reactive for about 1 h, then hypo-reactive after about 18 h, and lastly they become "tolerant" after about 30 h.

A second study was conducted to learn whether tolerance persists after return to water. Fish were kept in an 0.8% alcohol solution or water for 42 h as described. Experimental and control fish were then returned to separate water-filled tanks for 6, 24 and 48 h. After each interval, experimental fish were returned to individual tanks containing an 0.8% alcohol solution and controls were returned to individual tanks containing water. After 0·5 h, they were tested in the aversive stimulus trough. Another group of fish were immersed in alcohol or water for 24 h before testing. These periods were chosen because in the original experiment alcohol fish were maximally excited and maximally depressed at 0.5 h and 24 h, respectively. If tolerance persisted after return to water, reimmersion in alcohol could be expected to (1) abolish the excitatory phase at 0.5 h, (2) abolish the depressed phase at 24 h, or (3) do both. This did not occur. Tolerant fish, after return to water, still showed an excitatory phase after 0.5 h in alcohol and a depressed phase after 24 h in alcohol (Fig. 2).

As noted, fish occasionally failed to swim away from the light. The percentage of nonresponders in the experimental and control groups differed markedly. 9% of the alcohol group and 23% of the control group ($\chi^2=49.57$; $P<0.001$) failed to respond. The difference existed each time fish were tested (Table 1). To investigate this more deeply, we repeated the experiment with one change: two fish, instead of one, were placed in the small containers. Tested after 42 h of immersion (Table 1), the percentage of nonresponders was the same in both groups. A tank mate, in short, had the same effect as alcohol in reducing the number of nonresponders.

Table 1 Comparison of Nonresponders in Alcohol and Control Groups

Time in solution (h)	Alcohol group		Controls	
	N	Nonresponders (%)	N	Nonresponders (%)
0.5	75	7	75	12
1	62	8	62	16
2	62	8	62	10
6	61	3*	62	19
12	62	6*	62	26
18	60	12*	61	34
24	60	8	61	16
30	56	14	62	29
42	41	22*	47	55
42 (with two fish)	19	21	24	21

"Nonresponders" refers to fish that swam less than 5 cm from a start box in an aversive stimulus trough, the stimulus being a high intensity light. All fish were kept in single-fish tanks containing either alcohol or water, except in the final trial, when two fish were kept in each tank.

* Significant difference between alcohol and control fish ($P<0.01$).

It seems, therefore, that goldfish can become adapted to alcohol and that the initial response is biphasic. Tolerance of alcohol is rapidly extinguished if acclimated fish are returned to water. The excitatory phase may result from a rapidly rising blood alcohol level, but the depressed phase and subsequent tolerance apparently reflect duration of exposure, since blood alcohol concentration is constant after 1 h of immersion. Finally, "social isolation" of goldfish apparently reduces responsivity to an aversive stimulus, and alcohol cancels this effect.

Larval Development and Metamorphosis of *Acanthaster planci* (Asteroidea)

LITTLE is known of the factors influencing survival during the planktonic phase of *Acanthaster planci* (Linnaeus), the crown of thorns starfish, apart from an observation of fish eating newly released eggs[1]. But it is not surprising that this phase has been suggested as the cause of the recent plague of the animal in the Pacific[2–4], for large females release many millions of eggs each spawning season[1] and any factor which slightly reduces the mortality rate during planktonic life and settlement greatly increases recruitment into the starfish populations.

In this study *A. planci* was reared in the laboratory from fertilization to juvenile starfish and a preliminary study has been made of the influence of temperature, salinity, food and substrate on survival and development. Previously, Henderson[5] and Mortensen[6] reared *A. planci* to late bipinnaria and brachiolaria stages, respectively.

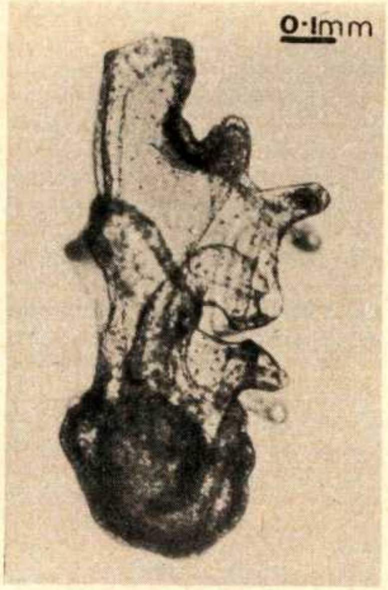

Fig. 1 Lateral view of an early brachiolaria of *Acanthaster planci*.

Mature starfish were collected from a cay 40 miles ENE of Cardwell, North Queensland (146° 51′ E, 18° 2′ S), on January 22, 1971; larvae were obtained by the method of Henderson[5]. On day 3 the larvae were transferred to 10 l. glass aquaria containing seawater, $33^{0}/_{00}$ salinity, with 50 IU penicillin G and 0.05 mg streptomycin sulphate/ml. A mixture of unicellular algae was added on days 3 and 9. On day 15 the larvae were transferred from the Fisheries Laboratory, Mourilyan, to James Cook University and placed in glass dishes, about 100 per dish containing 250 ml. of filtered seawater, in a shaker bath operating at forty-five shakes per minute. The larvae were transferred to fresh conditions every few days and unicellular algae added daily. Dishes were maintained at 24°–25° C until day 21, then some were raised to 28°–29° C by day 26.

Bipinnariae developed in the manner described before[5,6]. After day 23 some larvae developed two brachiolar arms on the pre-oral ciliated band; the pre-oral lobes enlarged, an adhesive disk developed and the posterior portion containing the starfish primordium became enlarged, irregular and brown (Fig. 1). The pre-oral lobe apex then developed dorsal and ventral projections, the latter becoming the third brachiolar arm (Fig. 2). Mortensen's brachiolaria[6] is similar, but the pre-oral arms are obscure and the primordium is poorly developed.

Late brachiolariae tested substrates with the brachiolar arms and settlement began on day 28. Some remained attached by the adhesive disk throughout metamorphosis; others either failed to attach or detached. Metamorphosis into a five-armed starfish, with absorption of larval structures, took two days. The early starfish were 0.3–0.5 mm diameter and each arm carried a red pigment spot, a primary podium and two pairs of tube feet on its oral surface (Fig. 3). Juvenile starfish, apparently still feeding on the unicellular algae, grew 0.1–0.2 mm in diameter in 10 days with subdivision of the arms and development of the mouth, spines and ossicles (Fig. 4).

Many larvae failed to reach brachiolaria or metamorphosis and regressed to a ciliated, globular form. Larvae completed development at 28°–29° C, while those remaining at 24°–25° C did not advance beyond early brachiolaria. The mean period from fertilization to starfish was 38 days with a range of 30 to 47 days. In other studies, *A. planci* larvae developed more rapidly, developing to late bipinnaria in 12 days at 27° ± 1° C[5] and to brachiolaria in 16 days[6]. Thus survival and developmental rate vary markedly within a small temperature range. Development may be more rapid in the field than in this study with a long period at 24°–25° C—Barrier Reef water temperatures are 27°–30° C during the breeding season.

A. planci bipinnariae tolerate abrupt salinity changes from $36^{0}/_{00}$ to $21^{0}/_{00}$[5]. Late brachiolariae and metamorphosing forms are much less tolerant and many ruptured when transferred from $33^{0}/_{00}$ to $35^{0}/_{00}$ salinity. The ruptures were invariably from the starfish primordium and earlier stages in

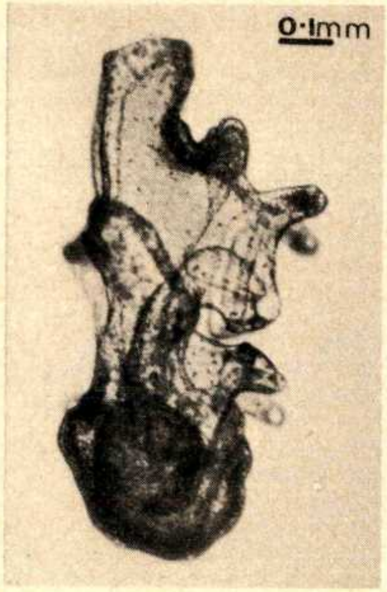

Fig. 2 Lateral view of a late brachiolaria of *Acanthaster planci* showing the three brachiolar arms (1) and adhesive disk (2) (preserved specimen).

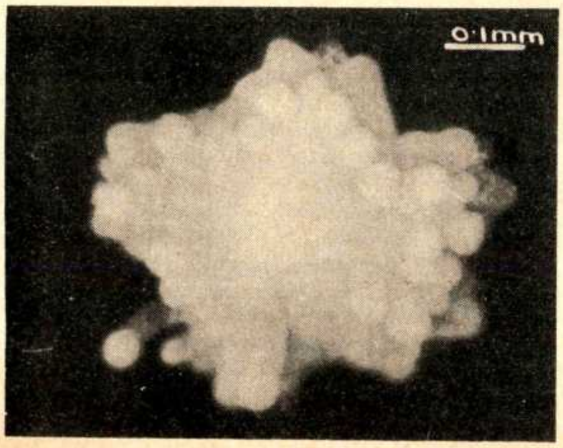

Fig. 3 Oral view of juvenile starfish of *Acanthaster planci* one day after metamorphosis (preserved specimen).

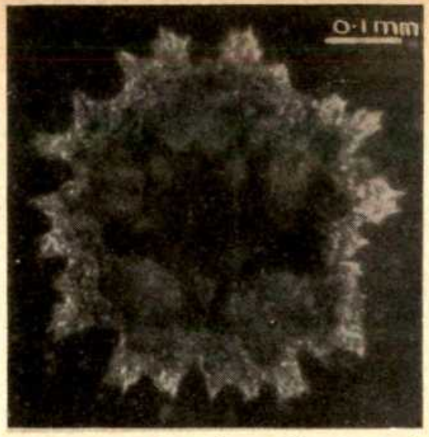

Fig. 4 Aboral view of juvenile starfish of *Acanthaster planci* 14 days after metamorphosis.

the cultures were unaffected. The metamorphosis of ruptured larvae was abnormal.

Larvae fed a mixture of unicellular algae, *Isochrysis galbana*, *Gymnodinium* sp., *Amphidinium* sp., *Cyclotella nana* and *Dunaliella primolecta*, had a predominance of the last alga in their stomachs and some were fed solely with *D. primolecta* from day 22. These larvae metamorphosed at the same time as those on the mixed diet.

Brachiolariae showed a degree of substrate selection at settlement, as observed in other echinoderm larvae[7]. Late brachiolariae kept for up to 14 days in clean, glass dishes without additional substrates failed to metamorphose and some regressed. Simultaneously larvae metamorphosed in other dishes in the presence of encrusting algae and algal detritus. With the exception of a larva which attached to an algal strand on dead coral, *Pocillopora damicornis*, larvae only settled on the bottoms of dishes and there was no significant difference between settlement rates in dishes to which the following substrates were added: macroscopic algae, *Cladophoropsis* sp.; serpulid tubes; fine, siliceous sand; lithothamnion; live *P. damicornis*; *A. planci* spines and tube feet and recently depredated *P. damicornis*.

The period of the *A. planci* life cycle between the earliest starfish, 0.3–0.5 mm diameter, and the smallest, field specimen, 11 mm diameter, collected from coral[1], is still to be studied. This important period includes the transition to adult feeding behaviour.

We thank Mr R. G. Pearson and Mr M. Lamont for their assistance and Professor C. Burdon-Jones for his advice in preparing the manuscript. The work was supported by the Government of Queensland and James Cook University of North Queensland.

New Hypothesis of the Cause of Cytoplasmic Incompatibility in *Culex pipiens* L.

IF males of one strain of *C. pipiens* are crossed with females of a strain from a different geographical area, the number of offspring may be either normal or small, or there may be none at all[1]. These three results have been called compatible, partially compatible and incompatible, respectively. Reciprocal crosses may give the same or different results. For example, strain A males may be fully compatible with strain B females, but strain B males may be compatible, incompatible, or only partially compatible, with strain A females.

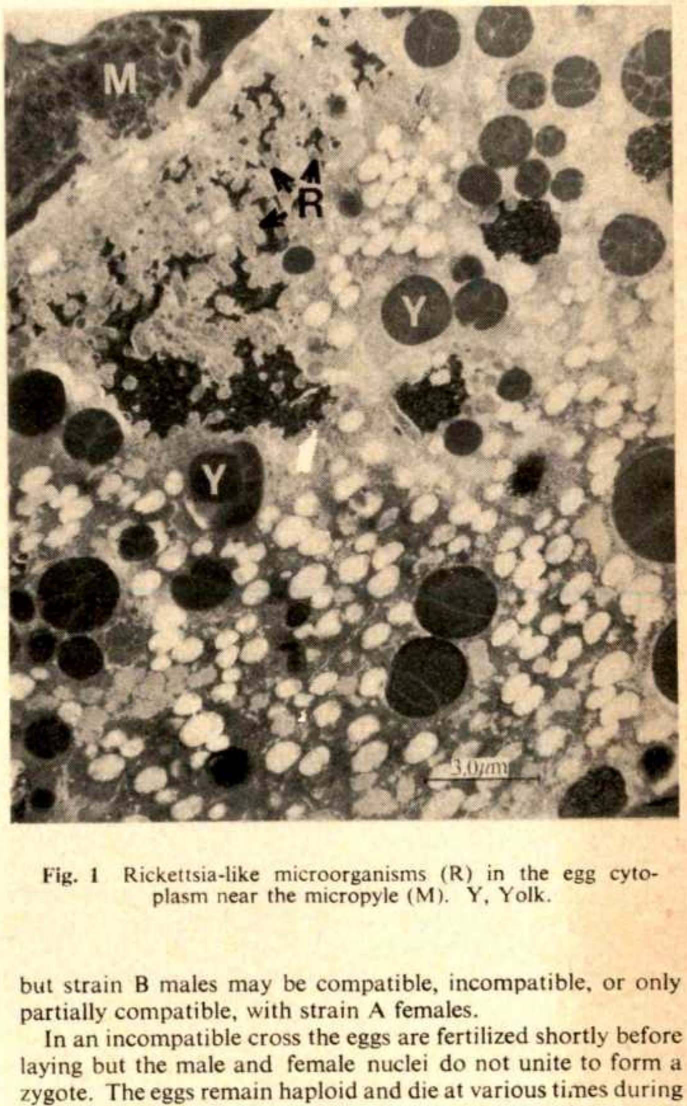

Fig. 1 Rickettsia-like microorganisms (R) in the egg cytoplasm near the micropyle (M). Y, Yolk.

In an incompatible cross the eggs are fertilized shortly before laying but the male and female nuclei do not unite to form a zygote. The eggs remain haploid and die at various times during embryogenesis[2]. Incompatibility is inherited strictly through the female, as shown by Laven's experiments on genome replacement[1]. For this reason the incompatibility is said to be cytoplasmic.

In a partially compatible cross many eggs die, sometimes before fertilization and sometimes after, so that embryonic death cannot be ascribed to haploidy[3]. It may be very difficult to distinguish between incompatible and partially compatible crosses. True hybrids may be produced in presumably incompatible crosses at a very low frequency, possibly once in 5 or 10,000 incompatible eggs (unpublished results of J. H. Y.).

Although a number of hypotheses have been put forward to explain the inheritance of cytoplasmic incompatibility, none of these offers an adequte explanation and none suggests how it might be caused[1,4,5]. We wish to propose a new theory based on a cytoplasmically inherited infectious agent. A rickettsia-like microorganism has been found in substantial numbers in the adults, eggs and embryos from normal and incompatible crosses of *C. pipiens*. These microorganisms are found in the follicles of the ovaries and in recently laid eggs, they are especially abundant near the microphyle (Fig. 1). They are approximately the size of mitochondria but of variable size. In sections prepared for electron microscopy they are seen to be elongate or spherical bodies surrounded by two membranes, and are often seen in association with accumulations of glycogen (Fig. 2). The sperms enter the egg through the micropyle and must pass near or through the mass of microorganisms before they can approach the female nucleus which lies midway down the length of the egg. It is possible that the microorganisms have a deleterious effect on presumably "incompatible" sperm so that they are unable to participate with the oocyte nucleus in the formation of a zygote. The microorganisms appear to be well adapted symbionts of their normal hosts, the particular strains of mosquitoes in which they are normally found, but may be deleterious to sperms of other strains.

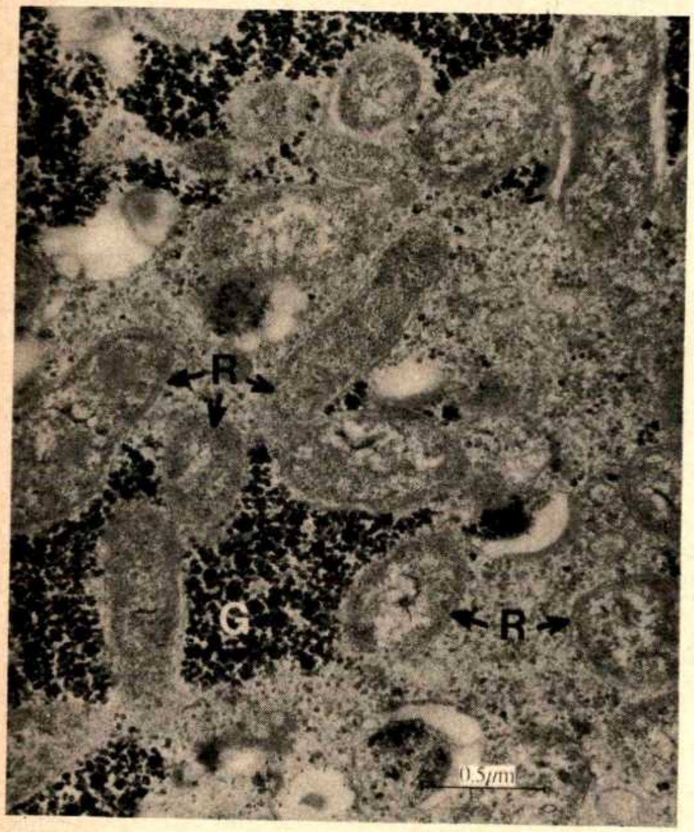

Fig. 2 Enlarged view of the microorganisms in the egg. G, Glycogen; R, rickettsia-like microorganism.

Hertig[6] described a rickettsia-like microorganism, *Wolbachia pipientis*, from *Culex pipiens* from Boston, Massachusetts. He also found them in specimens from Minnesota and China. Similar microorganisms have been found in other members of the *C. pipiens* complex, in *C.p. quinquefasciatus* Say in Colombia[7] and in the autogenous form of *C. pipiens* from England[7] and France[8]. Hertig failed to find them in other species of *Culex* in Massachusetts and Zulueta in other species of mosquitoes in England although he did find them in some species of forest culicines in Colombia. The microorganisms have been found in all the specimens of *C. pipiens* which have been examined.

The presence of coadapted combinations of *C. pipiens* and infectious agents may explain the spectrum of crossing types observed in *C. pipiens*. The microorganisms are consistently present in the reproductive organs of the mosquito throughout its life cycle and probably kill some follicles and sperm in each generation. If it is assumed that males and females of a strain of *C. pipiens* have the same strain of microorganisms but mosquitoes of different strains have somewhat different microorganisms, then in compatible crosses, the sperm of, for example, strain A which have survived the effect of the microorganisms in the developing testes, are not killed when they enter the eggs of females of strain A which contain the same strain of microorganisms. The sperm fuse with the oocyte nuclei and produce normal larvae. The same sperm from strain A when exposed to a different strain of microorganism, as, for example, in the eggs of strain B, are adversely affected and are prevented from forming normal diploid embryos. In these cases incompatibility is observed and the cross produces no offspring except for an occasional parthenogenetic female. In the reverse cross the effect on the sperm may not be lethal and in this case nonreciprocal incompatibility is the result. Partial compatibility is seen when the microorganisms of a strain of mosquito are not lethal to all sperms from another strain of mosquito. Some sperm survive passage through the mass of microorganisms and unite with the female nuclei to form diploid embryos although some of these succumb to infection later in embryogenesis. Hybrids which survive have gonads which are infected with the maternal strain of microorganism. The gametes they produce have survived the infection, so no effect of the infection is seen in F_2 matings.

The elucidation of the mechanism of cytoplasmic incompatibility in *C. pipiens* is of utmost importance because of its potential use in the control of medically important mosquitoes and because it may clarify our concept of speciation in the *C. pipiens* complex. Our proposed explanation for incompatibility provides a starting point for the solution of these two problems, control and speciation. Much work needs to be done to prove that the microorganisms do in fact cause incompatibility. Infectious agents are known to cause a number of unusual effects in other Dipterans such as sex-ratio distortion[9], CO_2 sensitivity[10] and male hybrid sterility[11]. Cytoplasmic incompatibility has also been found in the *Aedes scutellaris* group of mosquitoes[4] and a rickettsia-like microorganism has been reported from a related species, *A. aegypti*[12].

We have found a rickettsia-like microorganism, possibly *Wolbachia pipientis*, in eggs from incompatible and normal crosses of *Culex pipiens*. It is found in the cytoplasm of the eggs and other cells of the mosquito but not in mature sperms. The presence of the microorganisms in the maternal cytoplasm and their transovarial transmission suggests that they might be the cause of cytoplasmic incompatibility.

BOOK REVIEWS

Old World Revisited

Old World Monkeys (Evolution, Systematics and Behaviour). Edited by J. R. Napier and P. H. Napier. Pp. xvi+660. (Academic Press: New York and London, 1970.) £9.50.

THIS volume contains nineteen contributions from a symposium in Burg-Wartenstein (July 1969), sponsored by the Wenner Gren Foundation. The primary intention was provision of a basis for revising the systematics of Old World monkeys (superfamily Cercopithecoidea), and that aim has been admirably fulfilled. The papers provide an excellent source of up to date information on a number of key topics. In particular, it is invaluable to find in one volume a review of the fossil history of the Old World monkeys (Simons), a concise survey of biochemical aspects of monkey evolution (Barnicot and Wade; Sarich), an account of the oft neglected area of Sundaland (Medway), a series of papers on the behaviour of forest-living monkey species (Lowe's Guenon–Bourlière *et al.*; Drill–Gartlan; Gray Langurs–Ripley), a fascinating account of cross-species modification of social behaviour in baboons (Kummer *et al.*), and an annotated classification (Thorington and Groves). Among the behavioural papers, Struhsaker's account of the relevance of *Cercopithecus* vocalisations for classification is particularly noteworthy. Academically, the overall product is a highly useful and stimulating book, for which tribute should be paid to the sponsors and the editors. This book should prove to be essential for anyone concerned with Old World monkeys and their evolution.

Interest in biochemical aspects of Primate evolution is growing rapidly, and outsiders will find the balanced account provided by Barnicot and Wade both readable and informative. Evolution operates through modifications in the structure of DNA, and such changes can be directly expressed in protein structure. Ideally, an analysis of amino-acid sequences in various proteins should provide highly reliable data on evolutionary change. Actual sequencing is rare, however, and most workers estimate amino-acid change largely with electrophoretic techniques (Barnicot and Wade) or through immunological cross-reaction (Sarich). In spite of the limitations of such techniques, Sarich claims to be able to provide an absolute evolutionary time scale, given calibration of *one* point from the fossil record. It is unfortunate that he should have selected an extremely questionable date (that of the divergence of Cercopithecoidea and Hominoidea) for calibration, and that he should have proceeded to a controversial dating for the divergence of apes and man, where the fossil record is comparatively good. As Thorington hints in his introduction, new techniques of this kind are best tested by comparison with existing classifications, rather than *vice versa.* Eventually, biochemical data will provide a precise tool for investigating evolutionary relationships; but there are still many difficulties of *interpretation* to be mastered. Nonetheless, it does emerge quite clearly from both biochemical contributions that the New World monkeys are probably not separately derived from prosimian ancestors; although the date of divergence is not clear, it seems obvious that there was a specific stock which gave rise to all the monkeys and the apes.

A review of the fossil history of the Old World monkeys has long been overdue, and Simons does much to clarify a somewhat confused situation. There is, however, one conspicuous omission. Simons states that *Apidium* should be classified within the Cercopithecidae, and he has also suggested that *Oreopithecus* is a close relative of *Apidium* (Simons, E. L., *Scientific American,* **211**, 50; 1964). Since this implies that *Oreopithecus* is an Old World monkey (contrary to Hürzeler's interpretation), adequate treatment of this fossil would have been welcome. Simons also gives the impression that available fossils are sufficient for zoogeographical interpretation, which is not the case. His apparent conflict with the views expressed in Napier's stimulating discussion of palaeoecology and evolution should be viewed in this light.

Typographically, this book does not do justice to its academic importance. The mixture of (sometimes inaccurate) typescript with neat printing is unpleasing, and it is disruptive to find the figures and tables grouped at the ends of the papers. There are many typing errors, one of which has led to the surprising statement in Ripley's paper that "The food of the grey langurs consists primarily of termite clay" (page 486). Even on the book jacket, there is a reference to "ethololologists" (?). Presumably, the justification for this layout could be that of economy; but such economy is not evident in the high price quoted.

R. D. MARTIN

Drugs in Confusion

Drug Dependence. Edited by Robert T. Harris, William M. McIsaac and Charles R. Schuster Jr. (Advances in Mental Science II.) Pp. xiv+342. (University of Texas: Austin and London, November 1970. Published for the Faculty for Advanced Studies of the Texas Research Institute for Mental Sciences.) 95*s*.

IN spite of the title, this is a miscellaneous collection of papers given at the "second annual symposium sponsored by the Texas Research Institute of Mental Science". The date of the meeting is nowhere mentioned but from internal evidence it seems to have been in the first half of 1968. There are twenty-four contributions of varying quality, arranged under the general headings "Biological Aspects" (eight papers); "Pharmacological Aspects" (three); "Behavioral Aspects" (five); "Therapeutic Programmes for Drug Dependence" (five) and "Social Aspects" (three). If the first group is redistributed (drug dependence is a biological phenomenon), the last sub-divided into "Penal Aspects" and "Social Aspects", and one or two of the most obviously misclassified papers helped into more appropriate company, we get pharmacology, nine; behaviour, seven; treatment, two; law and punishment, four, and society, two.

This kind of "balance" is fairly representative of collections of this kind, and it may well be due in part to the difficulty of collecting hard data in soft areas; although it should be pointed out that "hard" is not necessarily synonymous with "reliable" or even "objective", and is seldom coincidental with "relevant". But of course the hard scientists always have the best of that argument—to paraphrase the little girl (or, some say, the old lady), they can and do claim "you can't tell if it's relevant if you don't give me a grant". Another kind of imbalance is more worrying, however, and it is hard to say if it is exaggerated or lessened by mixing scientists from different disciplines together in this way. I mean the trespassing of scientists, sometimes eminent ones, into fields of which they are not landlords, nor even tenants, and where they describe the scene, enunciate laws, or give directives on the authority of their absentee reputation instead of the evidence before them. Is it my own prejudice that social scientists are less inclined to this kind of bad manners than basic ones? Probably; for example, the only piece of discussion (of which there must surely have been more than this) that the editors have thought worth including follows a paper by the assistant director for science of the United States Bureau of Narcotics and Dangerous Drugs; their purpose in doing so is perhaps to remind him that the high tension passing through the barbed wire does not respect the direction from which the cow approaches it.

On the other hand, the two "social" authors seem to me to grow in stature by putting their roots down firmly on their side of the fence. Helen Nowlis, cool and wise as ever, emphasizes that there are two separate drug problems—a medical problem and a people problem; that student drug use is a social problem that extends far beyond drugs; and that "to rely on presenting the effects of drugs on the body is not enough".

Dr Bueno, on the other hand, ends his paper "The Problem of Drug Addiction (*sic*) in Mexico", and indeed the book as a whole: "their lies are so clear to their hearts and senses that I fear they'd rather die than renounce them, if not treated with intelligence, so strongly do they persist in their doctrines and superstitions". One might be pardoned for thinking that he is referring to the current debaters about certain problems of drug dependence; in fact, he is quoting from an early seventeenth century *Manual for the Ministers to the Indians.* Perhaps we need a twentieth century "Manual for Professors ministering to Each Other".

C. R. B. JOYCE

Inside Plants

Introduction to the Fine Structure of Plant Cells. By Myron C. Ledbetter and Keith R. Porter. Pp. ix+188 (51 Plates). (Springer–Verlag: Berlin and New York, 1970.) 54DM; $14.80.

LEDBETTER and Porter have produced an outstanding collection of plant electron micrographs. Probably no other laboratory in the world could bring forward a group of such sustained high quality across such a wide range of material. Such atlases, which have now been emerging regularly from various laboratories for about seven years, conveniently chart the progress made in the techniques for the preparation of plant material. That plant techniques have now, in the best laboratories, caught up with animal preparative techniques, can be demonstrated by comparing one of the first atlases (Stephen Hurry's excellent *The Microstructure of Cells* of 1964) with this production.

The text, however, which is generous compared with most atlases and well referenced, has limitations. The highly critical approach, applied to the quality of the micrographs, has not been applied to the text. Several statements are either wrong or misleading, for example, "Apparently the S_3 layer has a higher content of matrix substances (pectins, lignins and *sporopollenins*) . . ." (page 61); "The cuticle . . . is in turn impregnated with . . . waxes and oils, which . . . render it resistant as well to insect pests and the invasion of microbial and viral diseases" (page 109); "The large size of mesophyll cells is due in part to their relatively large vacuole" (page 133); "The absence of starch from the plastids reflects only the inability of permanganate to fix it . . ." (page 161); ". . . the Ubisch bodies, which are absorbed onto the surfaces of the pollen grains" (page 168).

Other statements may be true, but have no scientific backing to my knowledge, for example ". . . the plasmodesmata provide for the intercellular movements of large and small molecules . . ." (page 49); ". . . the Casparian strip assures that entering ions must pass through the plasma membranes of the endodermal protoplasts . . ." (page 81); "Cutin . . . Produced by epidermal cells, it moves through their primary walls and floods out over their exposed surfaces . . ." (page 113).

Plate 6.3 is labelled "Collenchyma". It is, however, a filament cell, at best a very atypical form of this type of cell and not representative in a number of ways. The structure of companion cells is given in detail, but no mention is made of the fact that they are absent in all gymnosperms, in a few angiosperms as well, and in all angiosperms in early stages of development. Cutin chemistry is much better understood than is suggested on page 113. Lignin (page 109) is an infrequent component of the epidermal cells of higher plants.

In short, the micrographs of this work and their references may be used as the most up to date and (with regard to the micrographs) the most technically accomplished of their kind available in a collected form. But the text must be treated with great care.

B. E. JUNIPER

Comfort of Clothes

Clothing: Comfort and Function. By Lyman Fourt and Norman R. S. Hollies. Pp. ix+254. (Dekker: New York, November 1970.) $14.50; £6.90.

THIS book is concerned with the interactions of clothing with the thermal balance between man's metabolic production of heat and his exchange of heat with the environment. Readers interested in this subject will doubtless be familiar with the classic *Physiology of Heat Regulation and the Science of Clothing* by L. H. Newburgh (Saunders, Philadelphia and London, 1949). The present book discusses more recent work which has added to basic knowledge of the subject, and includes information derived from studies of the comfort properties of military clothing conducted in government research laboratories in the United States and elsewhere.

The book deals exclusively with the interaction of "normal" clothing as worn by the military and by civilians in everyday life with the transfer of sensible and evaporative heat between man and his environment. It does not deal with special clothing using auxiliary power for heating or cooling inside the clothing (such as space suits) nor with the mechanical properties of clothing (strength, durability and so on).

The first chapter discusses various quantities and units used in clothing comfort studies, and the second considers clothing as a quasiphysiological system, including discussion of the air content of fabrics and clothing systems and the effects of wind and body motion on the thermal balance. The third chapter consists of a discussion of clothing types for different parts of the body.

The next chapter, concerned with heat and moisture relations in clothing, describes test methods involving apparatus and human subjects. The latter aspect of such studies is treated in more detail in the fifth chapter. There is an account of various physical properties of clothing and clothing materials in relation to comfort, including among others air and water permeability, flammability, static electricity and radiant heat characteristics, in the sixth chapter. Next, natural and man-made fibres are compared with respect to the comfort properties of fabrics made from them, and in a short final chapter the authors discuss briefly current trends and developments involving new materials and finishes, new techniques and new concepts of clothing design.

This book is an extensive review of published works with 477 references. For this alone it is valuable and will be useful to people concerned with the comfort of clothing in spite of a few misprints and errors.

W. H. REES

The Seas are Changing

The Sea: Ideas and Observations on Progress in the Study of the Seas. Edited by Arthur E. Maxwell. Vol. 4: New Concepts of Sea Floor Evolution. Part 1: General Observations. Pp. xi+791. £15.25. Part 2: Regional Observations, Concepts. Pp. xii+664. £15.50. (Wiley-Interscience: New York and London, June 1971.)

THE third volume of *The Sea*, edited by Maurice Hill, was published in 1963 and dealt with the Earth beneath the sea. It provided, and still provides, an excellent introduction to the techniques, theory and fundamental results of marine geology and geophysics. However, within a few years of its publication the whole conception of the origin of the deep-sea floor had undergone a complete revolution, and those parts of the third volume that dealt with ocean crust structure and evolution began to look in need of refurbishing. Now we have the fourth volume, dedicated to the memory of Maurice Hill, and entitled *New Concepts of Sea Floor Evolution*, which takes the appropriate parts of the previous volume, and revises and expands them in the light of the new plate tectonics. The expansion is considerable. What was about 500 pages now occupies 1,455, split into three parts and bound as two books. The first book contains part I, "General Observations", which is essentially a revised and expanded version of the material in the third volume, introducing some new topics, such as petrology and seismology, and concentrating on techniques and global summaries of results. The second book is new material. Part II, "Regional Observations", consists of a number of regional syntheses covering different parts, but not all, of the deep ocean floor and continental margins. The articles generally combine results from several geological and geophysical techniques to arrive at statements about the structure and origin of the areas under discussion. Part III, "Concepts", contains two articles, by Vine and Hess, and by J. T. Wilson, which set the general and regional observations into the global framework of plate tectonics.

A volume like this must have two distinct aims, to interest active scientists with new syntheses and ideas, and to build up a fundamental framework, to act as an archival source for the future. The first aim is not well met here, chiefly because of publication delays. Each article is dated, and dates range from April 1968 to July 1969, with most in the range July 1968 to February 1969. Things have moved a bit since then, in particular with the arrival of results from the JOIDES drilling programme in the deep oceans, and with the realization of the importance of triple junction evolution in the geological history of plate margins. Thus only a few of the articles make an impact as original and new, though in this class must come the thoughtful article on the structure of the Pacific basin by Shor, Menard and Raitt (book 2), and that on the benthic boundary layer by Wimbush and Munk (book 1).

The second aim, though of less immediate interest, is particularly important in determining the life of a book, and this aim is much better satisfied. Many of the authors have taken a great deal of trouble in assembling references, in giving accounts of results published in widely scattered papers, and in drawing the results together to make a solid framework. This is particularly successful in the section on regional observations, where such papers as that on the Mediterranean by Ryan, Stanley, Hersey, Fahlquist and Allan, and that on Pacific boundary structure by Hayes and Ewing will be invaluable as sources of assembled basic information. The price of the two books, £30.75, will be a considerable deterrent to the private purchaser. My own advice would be to make sure that your library gets both books, while if you feel that you can afford only one, buy the second book, with parts II and III, rather than the first. On the other hand, if you get a chance to review a copy, do not hesitate, it is certainly time well spent.

J. R. CANN

Cambrian Collection

Cambrian of the New World. Edited by C. H. Holland. Pp. 456. (Wiley-Interscience: London and New York, April 1971.) £10.50.

THIS is the first volume of a series designed to describe the Lower Palaeozoic rocks of the world. As Professor Charles Holland puts it, the intention is to provide an up to date, yet reasonably circumscribed survey illuminated by the authors' own views but retaining some measure of common organization. If the series can maintain the standard of the first volume this aim should be achieved with success.

The book contains six contributions: an account of the Cambrian of the stable interior of the United States by Christina Lochman-Balk; descriptions of the Cambrian of the Great Basin to the west and of the Cambrian of the Appalachians and New England to the east by A. R. Palmer, together with three chapters which summarize the Cambrian of Canada and Alaska, by F. K. North, of the North American Arctic, by J. W. Cowie and of South America, by A. V. Borrello. They are all clearly presented accounts, written by authors of considerable experience. Judging from the bibliography the text seems to have been completed about two years ago, but there is much new and previously undocumented material, particularly on the Cambrian of the west of North America.

An attractive feature is the manner in which the authors hand on unpublished material to their successors and go out of their way to point out the possibilities for future work which might lead to definitive syntheses. It is to be hoped that this approach attracts stratigraphical palaeontologists to the rich fields awaiting them. As Palmer remarks, as many as seven different biostratigraphical entities can be recognized in the Early Cambrian sequences of the Great Basin.

It goes without saying that a central theme in this book is the record of transgressions and regressions of the Cambrian seas over the Americas. At some time or another in the Cambrian, a part of every state in the Union was covered by a marine incursion. There are admirable syntheses of the different assemblages of rock which resulted and discussions of such topics as the possible influence of the underlying geological structures on the extent of these seas and repeated references to the interplay of biological activity and the kind of rock that resulted. Such discussions bring out the necessity to disentangle contemporary faunas which differ because they inhabited different environments from groups of animals which evolved through the passage of time and which might be used to define subdivisions of the Cambrian.

The reader is left with a clear picture of Cambrian events as revealed by present knowledge and with a sense of where progress is being made in current research and what the future might hold in store as investigations continue. Professor Holland and his colleagues can be congratulated on a fascinating book which I can recommend to any geologist interested in the Lower Palaeozoic history of our planet.

J. SUTTON

Physics and God

Proceedings of the International Conference on Thermodynamics held in Cardiff, UK, April 1–4, 1970. Edited by Peter T. Landsberg. (International Union of Pure and Applied Chemistry, in conjunction with the International Union of Pure and Applied Physics, and the Institute of Physics and the Physical Society. *Pure and Applied Chemistry*, Vol. 22, Nos. 3–4, 1970.) Pp. ix+215–555. (Butterworth: London, December 1970.) £9.

LET me say at the outset that I do not think that, purely academically, I am properly qualified to evaluate this book. I propose to review it, all the same, for the sake of interest and amusement: because it seems to me, as a modest but persistent user of commonplace thermodynamic methods in experimental physics, that this conference, which I did not attend, must certainly have been those things—and more. It illustrates the power of a simple macroscopic principle such as thermodynamics to

Pure Chemistry Library

provide a magnificent variety of all things from the profoundly philosophic through the simply utilitarian to the distinctly risible. It is sometimes difficult to distinguish (if one wishes or ought to) between the first and last of these. Take, for example, the following exchange in the discussion reports concerning the direction of time.

D. Park—(Massachusetts, USA)—It seems that we get our sense of time direction very much more from the radiation of the Sun . . . than from anything the Universe is doing. Why on Earth should non-radiative living processes be bound up with the ultimate fate of radiation? This is not clear in Landsberg's statement, but Narlikar has his own answer. According to it, if suddenly the Universe started to contract, then it would seem to us that, as a results of distant events, the Sun would start re-absorbing radiation.

Landsberg—It would seem so to God, not to living things. God would say, ah, the Universe is contracting and everybody is getting younger while, I, God, am getting older.

Costa de Beauregard—No! Eternity is time-extended!

Landsberg—Mon Dieu (laughter)! I didn't really mean God.

What shall our undergraduates, struggling grimly uphill on their Carnot cycles, make of this? It was not, of course, a conference for undergraduates, but that is a legitimate question, and the answer is, I hope, that they should make much—in the sense that these are the sort of deep philosophical problems that stimulate people to study physics—at least they provided one of my own major motivations and I do not think, in spite of appearances, that things are so very much different now, fundamentally. It is a pity that the glamour of particle physics and expensive accelerators, and the hubris apparently inevitably engendered in some of their adherents, have distracted attention from the equally—or more—fundamental questions raised by less expensive disciplines. It is also anomalous (in a rational, not a political) sense in this age of relevance: a good deal of the work of this conference might well have application in industry and elsewhere now and in the foreseeable future.

Rather few reports of conference proceedings have more than a transient appeal, as a collection of papers of current interest in a special field. This is surely one of them, which should be widely used and be of lasting value. The section on foundations is perhaps difficult and esoteric and will be read mostly by thermodynamicists, but there is wide interest in, for example, phase transitions and surfaces. There are papers on the theory of fading memory, irreversibility and quantum mechanics, astrophysics and relativity. There are papers and discussions on the teaching of thermodynamics. It is impossible to get an adequate idea of the scope and balance of the book, however, without examining it, which I very strongly recommend.

It seems a pity to carp, but I must say that this book is so valuable that an index would have been well worthwhile. It might have enabled me to detect some reference to information theory, which has so far escaped me. One other omission is the thermodynamics of finite systems. This state of matter, intermediate between non-interacting single-particle behaviour and the infinite thermodynamic limit, is surely of fundamental interest. It concerns, for example, nuclear matter, polymers, macromolecules and many biological systems, and could lead to a radical reassessment of our understanding. Not much is known experimentally in this area, but there is an awakening interest in the properties of small assemblies of particles, and this may well be a useful addition in a future conference.

D. F. BREWER

Information Science

Introduction to Science-Information Work. By C. W. Hanson. Pp. 199. (Aslib: London, June 1971.) £3; members £2.40.

ALTHOUGH information science has been developing rapidly during the past twenty years, and education in the field has been offered in the past ten years, there are still no definitive textbooks. It is a pity, therefore, that Mr Hanson, after his long pioneering experience at the British Scientific Instrument Research Association and at Aslib, as head of research, should now present a book on the mixed objectives of "information, documentation and library work" and called "science-information work". Information science is largely recognized as distinct from librarianship; in Great Britain, the term covers both practical and theoretical aspects, so that the expropriation of the term in the United States for theoretical studies of the science of information is not sufficient justification for abandoning it in Britain. Furthermore, information science is now extending into non-scientific fields, so that it is not just science-information. It was Mr Hanson who suggested the title "information scientist" in 1957.

Even as an "introduction" the book is quite elementary in content, although what it covers is most lucidly, carefully, and thoroughly described. It is in five parts. The first part deals with the problems of communication and the flow of information, the growth of the literature and the media of communication. The second part describes the primary and secondary types of literature, and non-documentary sources of information—organizations and people—a much-needed reminder in these days of mechanized services. There is then a rather short adumbration of mechanization, information retrieval and selective dissemination of information, all in a very general manner and in only seven pages. The fourth part discusses the provision of information to enquirers and users, and the making of searches for such information. Finally, there is some account of library operations, including lending, reprography and microforms in relation to information services; mechanized methods of library housekeeping are also considered. A short appendix gives attention to aspects of writing, editing, printing, publishing, translating and public relations.

In general, the book is centred on conditions in the United Kingdom, and foreign literature and sources of information are given scant attention. There is much sound commonsense in the advice given, but there are some unexpected flaws. The production of abstracts bulletins within industrial firms and research associations is not described. Patents are dismissed as unimportant as sources of information, although they frequently describe research which may not achieve wider publication for several years. To suggest that *International Critical Tables* (1927) is the last publication of its kind is too insular and ignores many excellent foreign publications.

The book is specifically addressed to school leavers, undergraduates and even older unqualified people, although information science is rapidly becoming a fully graduate profession. It deals too much with routine matters and makes the work seem rather a pedestrian activity. This is a pity, because the principal attractions of information science are the wide variety of tasks, the breadth of knowledge to be covered by keeping up to date and in touch with current research, and the contacts with people, from the factory floor to management. Increasingly there are opportunities to develop advanced computer-based systems, and there is a growing field of research in information science itself. Useful though this book may be at basic routine practical levels, it lacks the enthusiasm and the intimations of advanced work and problems which will inspire new entrants to the profession. Information departments, handling both technical information and management information, may well become the essential nerve centres of industry in the future. In the absence of the much needed advanced textbooks, even an "introduction" should point out, boldly, the way ahead.

J. FARRADANE

CORRESPONDENCE

Chemical Societies

SIR,—Your recent editorial about the Society of Chemical Industry (SCI) has just been brought to my notice (*Nature*, **231**, 411; 1971) and, as I believe I was the only individual member to protest against the proposed merger of the SCI with the other chemical bodies, may I explain why I did so? Other protests came from members of one of the sections of the SCI (*Chemistry and Industry*, 1592, December 12, 1970).

I am a member of the Chemical Society (CS) and SCI, but not of the Royal Institute of Chemistry (RIC) because I do not satisfy the professional membership requirements.

The original proposals were for the amalgamation of the three bodies under a new unifying charter and, as long as this was the case, I was in favour and voted accordingly in the CS referendum. As long as a new charter was the ultimate aim, any divergence on the way towards it was not important, for it seemed certain that the lawyers advising the Privy Council would sort out anything which ought not to be allowed. Suddenly, however, in a document issued to members by the CS, what was to be the new CS became the "new" CS and it appeared obvious that amalgamation under a new charter was not contemplated within the foreseeable future. As none of the bodies have power in their charters to amalgamate, any other kind of amalgamation was, therefore, unlawful.

As far as the CS is concerned, I am now waiting to see the scheme which the Charity Commissioners must be drafting for the uniting of two charitable bodies (CS and the Faraday Society) with two which are not (RIC and the Society for Analytical Chemistry). Because there is no power to amalgamate in the charter of the CS, this scheme will show how it can all be done through new bye-laws alone, which themselves may be inconsistent with the charter (Council Members "appointed by" the RIC against "electing . . . other Members of Council" by the Fellows; Fellows of "any nationality" against "loving subjects"). It will also show how these new bye-laws are to be approved at a meeting which, somehow, took place on April 21, 1971, when a resolution was passed for the new bye-laws to come into force forthwith. It will then reconcile that with the supplementary charter which says that "no such resolution . . . shall become effective . . . until the expiration of one month" and will then reconcile the whole with the original charter, which declares "no resolution or Bye-law shall on any account . . . be made . . . in opposition to the general scope, true intent and meaning" of the charter or of the laws or statutes of the realm (including the Charities Act, 1960?) and that if any such "rule or Bye-law shall be made, the same shall be absolutely null and void to all intents, effects, constructions, and purposes whatsoever".

How, in 1971, can the powers of the CS be so wide under its charter that it can amalgamate with (to be taken over by?) the RIC, when, in 1876, the "limited powers of the Chemical Society under its charter" were such that it could not accommodate within its own corporate identity that body of professional chemists which eventually became the RIC? (See *The Chemical Society 1841–1941*, pp. 52 and 53.) In any explanation, I hope account will be taken of the fact that the only thing which seems to have changed since 1876 is the addition of a supplementary charter in 1920 and that took away the class of associateship under which professional chemists might possibly have been accommodated.

In your editorial of November 14, 1970 (*Nature*, **228**, 597; 1970), you mention the "enormous expense of re-negotiating a single" charter. Could not some of this expense have been avoided (anyway, for those bodies which are charities—the CS and SCI) by asking the Charity Commissioners to prepare a scheme under section 15 of the Charities Act? This provides machinery for amending, free of charge to the charity, the charters of those charities which are established by Royal Charter. The idea is partly to stop charities needlessly incurring legal costs when the Commissioners can do what is necessary without charge to the charity. Charity money should be spent on charitable objects and anything the commissioners do for free means that just so much more will be so spent.

Yours faithfully,

J. C. WILLIAMS

Smoking and Cancer

SIR,—It would be a pity if the somewhat personal nature of the exchanges between Dr John Higginson (*Nature*, **232**, 355; 1971) and Dr T. D. Sterling (*Nature*, **231**, 543; 1971), about the availability of unpublished data on smoking and lung cancer, were to obscure a real point of principle involved.

A scientific author basing his conclusions on the results of an experiment takes it for granted that he has to publish enough information for the experiment to be repeated, and its results confirmed or not, as the case may be. In biology and medicine, and in the social sciences, conclusions may sometimes be drawn from observations which cannot be repeated, but here also the data ought to be made publicly available, to allow other interpretations. No useful scientific purpose is served by publishing unverifiable hypotheses; and that is so even if they are unverifiable only because the information needed for verification is kept private.

Ideally everything relevant ought to be published, but for reasons of space that may be impossible. As Dr Sterling has pointed out, this has not been done with most of the smoking/lung cancer investigations, and perhaps in other medical fields as well, where published conclusions have been derived from data which are not generally available, except by favour of the authors. This is unsatisfactory, since it is in no way to "impugn the integrity and competence of the numerous scientists and committees in many countries who have reviewed exhaustively the extensive data published on this subject" (if I may quote Dr Higginson) to accept that there is at least a remote chance that some of them may have been mistaken, and that there might be advantages in allowing a fresh look from an unprejudiced, or at any rate a different, point of view.

Granted that much of the data may be in a form unsuitable for publication in scientific journals, and that it would clearly be quite wrong to conclude that a busy and important medical scientist "who fails to make his data available to any Tom, Dick or Harry is lacking in credibility" (to quote Dr Higginson again), would it not be possible to have an arrangement whereby the data are deposited in some central library or institute and publicly available without reference to the author, to be copied and quoted from just as though they had been published with the original paper?

The British Museum (Natural History) has for many years operated such a scheme for biological and ecological data, which are often both voluminous and undigestible, and which journal editors are rightly reluctant to print, substituting instead a note to indicate where they are to be found in full. This seems to work well enough, and allows an author to refer to unprinted results without any fear of being accused of keeping them to himself, away from public investigation and criticism.

Yours faithfully,

C. B. GOODHART

Announcements

University News

Dr C. D. Papaliolios has been appointed professor of physics in **Harvard University** and **Dr David K. Cohen** has been appointed professor of education and social policy.

Professor F. M. Arscott, University of Surrey, has been appointed professor of pure mathematics in the **University of Reading,** in succession to **Professor R. Rado,** on whom the title of professor emeritus has been conferred.

Dr H. P. Rang, University of Oxford, has been appointed to the chair of pharmacology in the **University of Southampton.**

Dr W. M. Hutchison has been appointed to a personal professorship of parasitology in the **University of Strathclyde.**

Miscellaneous

The sixth annual **Karl G. Jansky lectureship** of the National Radio Astronomy Observatory, Charlottesville, Virginia, has been awarded to **Professor Charles H. Townes,** University of California.

The **Horace Le Marquand and Dudley Bigg research fellowship** has been awarded by the council of the Royal Society to **Dr G. R. Shellam,** Commonwealth Serum Laboratories, to enable him to study the immune response to tumour specific antigens at the Tumour Immunology Unit, University College London.

Special merit promotions have been awarded to thirty scientists and technologists employed in government and other public establishments: *Civil Service:* **D. Küchemann,** Royal Aircraft Establishment; **P. S. Bulson,** Military Vehicles Engineering Establishment; **J. F. Gittins,** Services Electronics Research Laboratory; **T. P. McLean,** Royal Radar Establishment; **R. J. Murgatroyd,** Meteorological Office; **D. W. Robinson,** National Physical Laboratory; **J. W. C. Gates,** National Physical Laboratory; **E. L. Goldsmith,** Royal Aircraft Establishment; **J. K. Lancaster,** Royal Aircraft Establishment; **K. R. May,** Microbiological Research Establishment; **R. L. Moss,** Warren Spring Laboratory; **J. B. Mullin,** Royal Radar Establishment; **M. E. Peover,** National Physical Laboratory; **P. B. J. Crisp,** Quantity Surveying Department. *Agricultural Research Council:* **F. Brown,** Animal Virus Research Institute; **C. G. Butler,** Rothamsted Experimental Station; **L. E. A. Rowson,** Unit of Reproductive Physiology; **A. Feinstein,** Institute of Animal Physiology; **J. W. B. King,** Animal Breeding Research Organization; **D. L. Lee,** Houghton Poultry Research Station; **W. G. Siller,** Poultry Research Centre. *Natural Environment Research Council:* **J. C. Swallow,** National Institute of Oceanography; **A. Watson,** Nature Conservancy. *Science Research Council:* **B. E. J. Pagel,** Royal Greenwich Observatory; **A. H. Gabriel,** Astrophysics Research Unit; **N. M. King,** Rutherford High Energy Laboratory; **P. F. Smith,** Rutherford High Energy Laboratory. *UK Atomic Energy Authority:* **R. Bullough,** Atomic Energy Research Establishment; **A. Gibson,** Culham Laboratory; **R. S. Nelson,** Atomic Energy Research Establishment.

Errata

IN the article "Gamma Rays (250 keV–2.3 MeV) from NP 0532" by L. E. Orwig, E. L. Chupp and D. J. Forrest (*Nature*, **231**, 171; 1971), the following corrections should be made. The end of paragraph 4 should read ". . . to account for the drift of the pulsar period as a result of the slowdown of the pulsar, the Earth's rotation, the Earth's orbital motion and the motion of the balloon". Paragraph 5, line 6, should read "$\gtrsim \pm 0.5$ ms", and line 4 should read "Another source of error . . .". Paragraph 6, line 3, should read "15 h 50 m 30 s UT . . .", and line 7 should read "15 h 50 m (29.9956 ± 0.0003) s . . .".

THE headline for the article "Formation of New Connexions in Adult Rat Brains after Partial Deafferentation" by P. D. Wall and M. D. Egger (*Nature*, **232**, 542; 1971) should read "Mapping of the receptive fields of cells in the thalamus and cortex after destruction of a dorsal column nucleus in the rat reveals evidence of functional reorganization in the central nervous system." The penultimate line of the legend to Fig. 1 should read ". . . the axes show distances".

PROFESSOR D. GWYNNE EVANS was mistakenly referred to as Professor D. Gwynne in University News in *Nature*, **232**, 508 (1971). Professor Evans is the director designate of the Lister Institute, as well as its professor of bacteriology and immunology.

Making Water Run Uphill

THE Annual Meeting of the British Association this year will not be the last or even the last but one, and indeed, if the programme arranged for Swansea is anything to go by, the occasion could mark a change in the association's intellectual fortunes. For a great many years, people have complained with some justice that the association's most spectacular public performance had become too dry and too academic to command the interest of younger professional scientists or even to enliven public awareness of what the association is for. Adversity seems to have brought out the best in the old organization, which for the past few years has steadily improved the sheer mechanics of presenting a kind of review of what is happening in professional science to an audience of interested bystanders and professionals. At the same time, the organization has taken, admittedly a little late in the day, some steps to put its constitution in order. That there should be talk of electing the members of the association's governing body, which has previously perpetuated itself from decade to decade, is a sign of how far the reforming spirit has gone. Yet it remains the sad truth that the sheet anchor of the association in the past few years, the annual subvention of £12,500 from the Department of Education and Science, is likely to end a year and a half from now. What will happen then? Will the British Association founder altogether? Or will it find some other way of carrying on?

The first thing to be said about the latest misfortune to befall the British Association is that it is not a misfortune at all but an opportunity. By all accounts, the Department of Education and Science has taken the view that if there is a public need of a forum for the discussion of issues in professional science or even in the relationship between professional science and society at large, then the government has itself made provision for this need in the setting up of committees such as the Council for Scientific Policy. Although there is plainly a great difference between the functions and the styles of the two bodies, there is something in this riposte. At the same time, the Department of Education seems, in saying no to the association's most recent request for money, to have declared that if public funds are to be spent on educational objectives, they had better be spent through an agency more directly under Mrs Thatcher's thumb. Galling though it may be for the British Association, and the host of voluntary workers who have over the decades helped to sustain vigorous programmes of what may be called local education, this is also a fair if ungenerous point. Indeed, what the Department of Education and Science is saying is that it would itself prefer to organize the machinery for carrying out the functions for which it is directly responsible. As a principle of public administration, that point of view is quite impeccable, for then everybody can be sure that responsibility lies squarely where it belongs. But there is also a political reason for this rigour. Why should a government trust a voluntary body such as the British Association to do its bidding—and why should a voluntary body such as the British Association assume that it will never be in conflict with the government even on matters such as the education of the young and the enlightenment of the public?

The truth, of course, is quite the opposite. If the British Association has a place in British public life at all, it must surely stem from precisely the kind of independence that must affront politicians of all parties. At the beginning, in the early nineteenth century, the British Association came into existence because of the conviction of its founders that the institutions of the establishment, the government departments and the Royal Society included, were unable to tackle problems within the scientific profession and problems of the relationship between professional science and the wider community. In the half century that followed, the association built up a powerful record of achievement. Not only did it sponsor programmes of scientific research of great distinction—the Gassiot committee, one of the best known of the Royal Society's standing committees, is, for example, a legacy from the British Association—but it also served as a valuable means of awakening public interest in professional science. The principle that members of the association may be entirely unqualified as scientists is a relic of the best of nineteenth century liberalism. It is, of course, anomalous and disappointing that with the passage of decades, the involvement of the British Association with the problems which it first of all set out to tackle has if anything diminished even though the need has grown.

This is the analysis which the association should not shrink from at its present meeting in Swansea. Over the years, there has grown up a tendency to believe that everything would be different if only some sufficiently resourceful man could make impossible economies or wheedle improbable benefactions out of private industry. The job that needs doing, as much now as in the early nineteenth century, is, however, one that requires independence, both from government and from industry. In the past year or so, it is clear that a sufficiently alert organization such as the British Association could have helped to clarify questions such as the advisability of investing public money in the new accelerator at CERN (an issue which is still evenly balanced), the issue of what should be done about the organization of the research councils and the decision (scandalously delayed) on the future scale of university finance and the relationship between universities and the polytechnics. British public life, not merely British science, is impoverished by the lack of an informed and influential platform from which questions like these can be argued intelligently. Moreover, there is every sign that the scientific community would be prepared to invest not merely money but time in organizing such discussions. The fact that so many people troop devotedly and usually at their own expense to the annual meeting of the association is a sign of what wellwishers are prepared to do. To say that the British Association should become a kind of pressure group is to go too far, for these are not circumstances in which there is a single consistent point of view to be advocated. But these are circumstances in which intelligent public discussion is bound to be a social benefit, both for professional scientists and for the community at large. To let this potential role go by default would be a loss for British public discussion as well as a tragedy for the British Association.

But how is it possible to do ambitious things without a budget? This is what the accountants are bound to say. Undoubtedly there is much that could be done to turn this criticism by strictly business stratagems. At the same time, however, it is essential that means should be found for simplifying the association's constitution. The issue is not whether the sixteen sections into which the proceedings are divided should continue to exist, but whether there is some device for allowing the organization as a whole to act decisively when its own interests and those of its members call for something to be done. At the same time, ways must be found of convincing even busy working scientists that the association can do something to further the common cause of a healthy scientific community in an appreciative and responsive setting. In attempting all this, organization in the ordinary sense is much less important than publicity of the right kind, but everyone knows that to say as much will offend against the over-modest dissembling of the British Association's members. This is why it is to be hoped that the annual meeting in Swansea will find people prepared for the radical departures from past policy that the circumstances warrant.

The Next Step with Nuclear Explosions

THE French government has done the decent thing in bowing to public pressure and cancelling the series of nuclear explosions planned for the next few weeks in the atolls of the Tahiti group. For one thing, of course, it is intolerable that the government of France (like that of China) should continue to release large quantities of fall-out into the atmosphere without acknowledging that to do so is to create a public nuisance. This, after all, is a form of pollution that justifiably merits concern. Protests at the impending explosions from neighbouring regions in the Pacific may have helped to change the French government's course of action, but it is also probable that the time is coming when the Gaullist view of the utility of nuclear weapons is fading. It is a long time now since the strategic justification of the French independent nuclear force was argued with enthusiasm. For one thing, it has turned out to be a costly way of hoping to make sure that in the event of an aggression, it would be possible for the military forces of France "to tear an arm" off the enemy before sinking beneath a hail of nuclear explosions. Second, nuclear weapons seem increasingly irrelevant to the military problems of Europe, especially now that the gap between East and West has been bridged to some extent by the continuing civility of relations in central Europe and by the signature last week of the agreement between the Occupying Powers on the future of Berlin. Third, the French nuclear force tends to be a device within the framework of an increasingly united Europe (and the British nuclear force, now almost forgotten, would be equally an irritant if it were ever advertised). In short, the government of France would be well advised to wash its hands of nuclear weapons at this stage of the game. Enough has been done to show that the properties of nuclei are the same in France as elsewhere. Not nearly enough has been done to make use of them.

In these circumstances, the time has come rather to ask what arrangements will in future be made for regulating the uses made of nuclear weapons. It is getting on for a decade since the partial ban on nuclear tests was negotiated, and the International Atomic Energy Agency in Vienna is now up to its eyes—and some say buried—in the intricacies of policing that unsatisfactory agreement. In the year just ended, the agency took over responsibility for policing safeguards agreements at about a hundred nuclear installations. According to the annual report for the year just past, it spent a total of $1.7 million on the work, and the budget for the coming year, also now published, suggests that this will rise to $2.6 million in the next twelve months. As always, the agency's abiding problem in the implementation of the safeguards policy is the recruitment of sufficiently skilled people and the determination of the conditions under which they should work. Optimism at Vienna runs as high as ever, but it is hard for outsiders easily to accept that the agency would be able to police effectively safeguards for a world in which the number of nuclear power stations under its authority was counted not in tens but in thousands.

This is why it is heartening in the past few months that the subcommittee of the UN Assembly on Disarmament, meeting at Geneva, has taken up again the issue of extending the partial test-ban to include all experimental nuclear explosions, whether underground or in the air. Not merely would this device let the Vienna agency escape from the invidious position of policing the unpoliceable into which it has been jockeyed, but it would solve a host of other problems, from the proper balancing of risks and benefits in some of the newer developments of military technology—multiple nuclear warheads, for example. Moreover, an extension of the test-ban would help to ensure that the asymmetries incorporated in the present treaty, and which in particular allot privileged positions to countries which have already manufactured nuclear weapons for themselves, will not at some stage lead to demands among the non-nuclear powers that they too should have weapons to themselves. In this sense, the non-proliferation treaty remains what it has been since its conception (and what its preamble says it is)—a temporary expedient.

As it happens, technical developments are also favourable. The article on page 51 by Dr F. M. Anglin shows how it is now possible to discriminate more accurately than previously between earthquakes and nuclear explosions with less than the equivalent of 10,000 kilotons of energy. The idea (see page 8) is that even quite small explosions can be distinguished from earthquakes of comparable size by the high frequency parts of their seismic spectra. To be sure, nobody would pretend at this stage that all explosions can be distinguished unambiguously from naturally occurring earthquakes, but there has been an immense improvement in the technology of test detection and discrimination since the days when the non-proliferation treaty was first advanced.

Making Voters of Universities

THE United States Senate has done as much as any legislative body can to endear itself to academics. It remains to be seen whether it will be able to persuade other politicians in the United States, and especially the Administration, that the time has come to be generous once again to colleges and universities in the United States. Two weeks ago, more or less with acclamation, the Senate passed the draft of a piece of legislation intended to replace the Higher Education Act of 1965, and which would have the effect, for the first time, of making attendance at an American university into an assurance of a maintenance grant, at least for students whose parents are not too well off. But as well as helping needy students, the proposed legislation would help needy universities and colleges—those on the institutional breadline would be helped not merely with matching grants to accompany the student grant but also with special awards in times of trouble (see *Nature*, **232**, 518 ; 1971).

By backing this bill, the Senate has done three important things. First, for the first time, it has declared that higher education in the United States is something which the federal government must worry about. So far, apart from some of President Johnson's devices for helping universities in need by providing funds for libraries and other special facilities, the operations of the National Science Foundation and the other research bodies which for practical purposes support graduate education but only fitfully, and the scheme for guaranteed student loans introduced a year ago and still too new to be assessed, the United States Administration has traditionally taken the view that good colleges and universities will be able to swim and the others deservedly to sink. It will be interesting whether the Administration, Republican as it turns out, will accept an argument that has failed in previous Congresses to enchant its predecessors.

The Senate has also affronted a great many of those who believe that higher education, like the operation of supermarkets, should find its own level by proposing that a large amount of money should be spent on subsidies. On present estimates, the new higher education bill, if it ever becomes law by the summer of 1973 (when the present Act runs out), would provide $18,000 million over three years. Many of those who have accepted the principle that higher education should properly be a charge on the federal government have found their hands rising in horror at the prospect that the rate of public expenditure on universities and colleges should rise to such a point that it exceeds even the spending of the National Aeronautics and Space Administration and other similar agencies. But, of course, this is only one side of the coin. The better half of the case is with those who argue that if a government such as that of the United States can spend $5,000 million (at the peak in 1968) on getting to the Moon and related activities, surely it can find a comparable amount to ensure the intellectual future of American society and industry.

That, of course, is the rhetoric. The interest of what the Senate has done, so soon after a period in which universities of all kinds and research academics in particular have been acutely short of funds, is that it presents the Administration with an important political challenge. A year from now, when the Senate's bill should have found its way through yet another round of committees and should have struck a response from the House of Representatives as well (where similar ideas are waiting in the wings), President Nixon will be up to his neck in the election that will decide whether or not he will spend a second term at the White House. Although there is no strong tradition, in the United States or anywhere else, that higher education can become a political issue, next year may provide an exception. After all, the past few years have done very little to heal the breach between the present Administration and the universities which was created as much by brashness and bad manners as by malevolence in the early days of Mr Nixon's Administration. It is improbable that Mr Nixon will now willingly take the risk of giving offence in the universities even if he manages to return from Peking next spring with quite unexpected political triumphs. In all the circumstances, this may be an occasion when the Administration finds it prudent to let the Senate have its present bill.

---

100 Years Ago

PARIS

Académie des Sciences, August 21.—M. Faye in the chair.—M. Chabris has calculated the quantity of nitrate of ammonia yearly carried down to the soil for the nutrition of plants by means of the rain to be two pounds of nitric acid, and consequently, three pounds of nitrate of ammonia per acre.—M. Dumas contributed to the Academy a piece of bread, the provision for the army, which had been infected by *Oidium aurantiacum*. Such facts are not exceptional, principally in very hot weather, and may be detrimental to the public health, as the fungus spreads very rapidly, and it is very difficult to get rid of it. A special committee has been appointed to prevent the infection if possible. MM. Dumas, Baron Larey, Tulasne the botanist, and Pasteur, the celebrated author of so many works on spontaneous generation, are members.—M. Berthelot has examined most carefully a piece of carbon from the Cranbourne meteorite, an Australian stone, and shows by many scientific arguments that the Cranbourne carbon is quite unlike the Orgueil meteorite carbon (a French specimen). The Cranbourne carbon must have been acted upon by a high temperature in ultra-terrestrian space, and no trace of organic origin is to be found on it.—M. W. de Fonvielle sent through M. Leverrier a note establishing that meteoric phenomena analogous to the Marseilles phenomenon are not exceptional cases.—M. Bert, the former Prefect of Lille during the war, described some most interesting experiments on the effects of pressure in suffocating animals living in a confined space. The rapidity of death is not the same for every kind of animal. If the pressure is very high the death is not due to any mechanical effect or to the want of oxygen, but to the presence of carbonic acid, resulting from respiration. It is poisoned by the produce of its own lungs.—The Academy held a secret committee for the nomination of a free member. The list of candidates long delayed was at last published, and M. Belgrand is at the head. But the nomination will be contested.

From Nature, **4**, 380, *September* 7, 1871

OLD WORLD

POLLUTION

Swansea Syndrome

A GRANT of £11,000 has been awarded to Mr G. T. Goodman of the Department of Botany at the University College of Wales, Swansea, so as to continue his investigation of non-ferrous metals in mosses, grasses and soil. A first report of this study, in the region around Swansea, appeared in June this year (Goodman, G. T., and Roberts, T. M., *Nature*, **231**, 237; 1971). Now the Natural Environment Research Council is prepared to support an extension of the study to the rest of Britain.

The original discovery showed the presence of large amounts of metals such as zinc, lead, cadmium and copper in plants and soil to the east of the Swansea Valley. At one of the most heavily contaminated sites, for example, some mosses contained as much as 1,200 parts per million of zinc, 800 parts per million of lead and 40 parts per million of nickel. One bizarre accompaniment of the investigation was the discovery that several horses found dead in a field near Llansamlet in the spring of 1970 had large concentrations of lead in their systems, although it has not been possible to show beyond dispute that lead poisoning was responsible. Malnutrition is another possibility.

The appearance of the article by Goodman and Roberts has led to several decisions, not the least important of which is the setting up by the Welsh Office of a working party on pollution by metallic elements in and around the Swansea Valley. It is assumed that the high concentrations of metal elements in the region have been caused by windborne pollution from neighbouring slagheaps, but another possibility is that exhausts from chimneys are responsible.

The working party is interdisciplinary in outlook and the scientists under the chairmanship of Dr R. T. Bevan, Chief Medical Officer at the Welsh Office, include Dr D. H. Peirson of the Atomic Energy Research Establishment, Harwell, Dr S. R. Craxford of the Warren Springs Laboratory, Professor C. R. Lowe and Dr J. R. Glover of the Welsh National School of Medicine, Professor P. J. Lawther of the Medical Research Council and Mr G. H. Francis of the Agricultural Development and Advisory Service. The first meeting of the working party was held in July and the second is scheduled for next week. The brief given to the working party was to recommend to the Secretary of State for Wales the sort of research programme needed to be set up to extend the work of Goodman and Roberts with particular reference to any correlation that might be established between the presence of heavy metals in the environment and human and animal life.

A member of the working party said this week that several botanical sampling stations would be set up throughout the area and that direct air sampling would also be carried out. Soil and herbiage samples would be analysed and blood and urine samples would be taken from hundreds of people throughout the area. It is planned that this survey will take twelve months to complete.

The simplicity and effectiveness of the technique developed by Goodman and collaborators make it particularly suitable for determining heavy metal contamination over even a short period. In areas that are moss deserts—because of high pollution—it is possible to deposit moss samples for as little as two weeks and obtain information on the accumulated metals during this time. The inexpensive nature of this research—the original investigation was carried out on a £500 budget—makes it a particularly useful tool to monitor atmospheric pollution. The problems in the Swansea area, however, might turn out to be insignificant compared with those found elsewhere in the country but there is no doubt that the working party will highlight the effects and dangers of a high atmospheric heavy metal concentration.

EMPLOYMENT

Graduate Problems

FIRST reports from the universities suggest that the plight of applied scientists may not be as bad as was predicted earlier this year. But times are still hard for pure scientists. In April the Confederation of British Industry (CBI) predicted a cut of between 15 and 20 per cent in the largest traditional field of graduate employment—industry and commerce. At the same time, several companies cancelled their visits on the traditional "milk-round" to British universities.

Now that the degrees examinations are over, what is the situation? The university appointments boards emphasize that it may be too soon to know for sure, partly because some graduates are on holiday and not bothering to look for jobs and partly because they often do not let their appointments boards know after they have accepted a job. But the impression is that it has been a difficult year. Quite how difficult depends on where you look. At Oxford, Mr T. Snow, the Secretary of the Appointments Committee, said that "graduate unemployment is not a problem". But he does admit that there are fewer jobs, particularly for those who want specific careers. It is particularly hard for chemists who want to remain chemists.

The estimate of the size of the problem varies from university to university—at Sussex, for example, Mr I. H. F. Kerr, the Appointments Officer, described the situation as "very serious" and estimates that as many as 400 of the 900 ex-students may still be job-hunting. At East Anglia, the number still looking is "higher than last year, but not dramatically so", while at the University of Manchester, figures for mid-July show that the applied scientists—with the notable and unsurprising exception of aero-engineering — were managing as well as or only slightly worse than last year, but that the pure scientists are finding it very bad. Half of the physicists are unemployed, however, compared with a quarter last year, and two-thirds of the chemists compared with half last year.

Yet things are not disastrous and there are hopeful reasons. The employers' concept of a "graduate job" is beginning to change. Companies are considering graduates for jobs that people with A-levels would have had a few years ago and they are also more ready to accept applicants with any degree, not just in a specific field. Graduates are equally beginning to look at careers that formerly they would not have considered — chartered accountancy, insurance, banking and local authority work. And for the graduate who is prepared to be flexible there are still jobs available. The University of Manchester's latest Clearing House List has some 1,400 vacancies (although this is a drop of between one third and one quarter on last year). Many science students are turning to completely different fields — British Rail travel planning or the Civil Service, for example. The theory that a university degree is a passport to a certain sort of job seems now to be a dead duck. Today there are even graduate shift foremen in a steel firm near Cardiff.

But if the employment situation is difficult, what are the graduates doing? Many are still on holiday or doing temporary work, and will only start looking in the autumn when the situation may well be worse, not better. Others may be trying to postpone the decision by prolonging their education. There has been an increase of more than twenty per cent in graduate applications to teacher training colleges—nearly 14,000 have applied for an estimated 9,000 places. (The new requirement that teachers in secondary schools should have a Dip.Ed. may help to account for this.) Some appointments officers also suspect that more graduates are simply dropping out, saying that "no job is better than any job".

SCIENCE COLLEGE.

CALCUTTA

INDUSTRIAL RELATIONS

Jack Hill

THE dismissal of Mr Jack Hill's case against his employers highlights the predicament of up to 60,000 engineers throughout the country. Mr Hill, a sixty-three-year-old contracts engineer with the Newcastle upon Tyne engineering company of C. A. Parsons, was given a month's notice at the end of July for refusing to join the Draughtsmen's and Allied Technicians' Association (DATA) which, after a three-year battle, had won the right to a closed shop at Parsons. He sued the firm for wrongful dismissal.

Mr Justice Brightman, before whom the case was argued, concluded that under the present law he could not prevent the company from dismissing Mr Hill. He added that if the law had allowed, he would have granted the order. Under the Industrial Relations Act, which comes into force by stages from October, the action of C. A. Parsons would be illegal. Mr Hill is appealing against the decision, but it is likely that the appeal will be heard before the relevant clause of the new Act comes into effect. Until the appeal is heard Mr Hill retains his job.

There are thirty-eight engineers at Parsons in the same position as Mr Hill, but the United Kingdom Association of Professional Engineers (UKAPE), of which Mr Hill is a member, is only too aware that as many as 60,000 engineers in 5,000 companies around the country are in a potentially similar position. They are all a minority body of professionals in companies with large numbers of technicians belonging to unions such as DATA.

UKAPE sees itself as protecting the professional ethics and integrity of senior engineers and feels that some of the aims of the Amalgamated Union of Engineering Workers, of which DATA is a part, are directly opposed to that integrity. As things are, UKAPE seems to be able to say plenty but to do little—its membership is not all that large. But if those whom UKAPE considered as professional engineers—those with degree or equivalent status—are to protect what they consider to be their rights, then once the Industrial Relations Act comes into force they will have to join UKAPE if they are to have any say in negotiations between management and the proposed agency shops. Otherwise they will find themselves out in the cold, a minority without national support among a hostile and militant trade union. In such a situation, UKAPE could become a force to be reckoned with.

The circumstances of professional engineers are by no means unique. Chemists and physicists working in industry could find themselves in the same position. So far, to be sure, they have not had to deal with unions as militant as DATA, the members of which worked to rule twice and struck once in their efforts to establish a closed shop at Parsons.

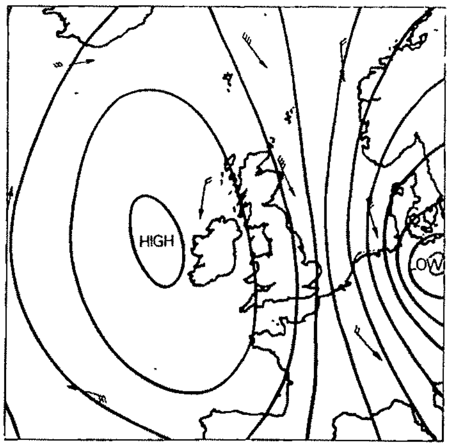
An Association of Professional Scientists and Technologists is being formed as a trade union (like UKAPE) although it will not be affiliated to the TUC (also like UKAPE) so that it can protect its members in the agency shops. But if Mr Jack Hill stands as one of the last—if one of the most spectacular—victims of the present law, it may transpire that his case is only the opening shot in a battle to come, for although the Industrial Relations Act will prevent closed shops in their present form, there are some fears that militancy will find other ways of achieving the same result.

RIVER FLOODING

London Sits and Waits

LAST week, five British Government departments issued a joint circular spelling out the consequences of the flooding of the Thames. It recommended all organizations likely to be affected to review their precautions and outlined the warning system at present in operation. London seems still to be in danger seventeen years after the Waverley Committee urgently recommended that it should be protected. Three hundred people died the year before, when the Thames Estuary flooded.

The Waverley Committee had good reason to be concerned. If the present level of defence was overtopped by 1 foot, serious flooding would result, with damage likely to be in the order of £1,000 million quite apart from the potential loss of life and the inconvenience of having London partially paralysed for up to nine months. The area theoretically in danger in the worst predictable combination of circumstances is that below the 23 foot contour. This is an area of 60 square miles and 1.2 million people, with 15 power stations, 4 sewage plants, 23 storm-water pumping stations, 56 telecommunications buildings, 46 miles of underground and 70 stations, almost all Government departments and the Houses of Parliament. The problem arises first because South-East England is settling so that the exceptional high water mark is rising at the rate of about 2.43 feet a century and second because of the power of the North Sea surges, usually caused by an intense depression from the Atlantic closely followed by a high pressure area. If the low pressure trough, on reaching North-East Scotland, swings south-east over the North Sea, the surge, amplified by the continental shelf, the comparatively narrow channel and strong winds, rushes down the North Sea and into the first convenient opening—the Thames. Every depression causes a surge, although usually a minor one. Should such a happening coincide with a high spring tide, and if the river were also full after heavy rain, the results could be disastrous.



Pressure conditions that will tend to induce Thames flooding.

At present there is a complicated five-stage system giving warnings ranging from a 12-hour-preliminary to a one-hour-final in Central London. The preliminary warning is given between 20 and 25 times a season, the three-hour Central London warning has been given only three times in the past five years. Given the present circumstances, the system seems as satisfactory as possible.

The government is at present paying 65 per cent (the Greater London Council is paying the other 35 per cent) of the £5.5 million needed to raise the riverside walls eighteen inches—the first time they have been raised since 1930. This will be completed in just over a year—the odds that the present level will be reached are about 1 in 10 in any year. With the new walls built, the odds of there being six inches of flood water in any one year will be 1 in 110. To provide what the GLC describes as an acceptable level of protection—7,000 to 1 in any year or 100 to 1 in a man's lifetime—the walls would have to be raised 6 feet, which is clearly unacceptable.

The alternatives—to build a barrage or a barrier—have been bandied about various committees and engineering companies since 1954. The government has recently approved the construction of such a barrier, which is now being designed, at Silvertown in the Woolwich Reach. Design is expected to take another eighteen months to two years, and construction a further five, at a cost of about £50 million.

NEW WORLD

Patent Policies Aim to Provide Incentives to Industry

by our Washington Correspondent

A POLICY designed to enhance the likelihood that research financed by the taxpayer will be commercially exploited was announced last week by the Office of Science and Technology. The new policy should delight private corporations, which now have the chance, under certain circumstances, to gain exclusive licences for exploiting government inventions, and it should also clear up a few vexing irregularities in the Federal government's attitude towards the granting of patents on inventions arising out of government sponsored research. Described by Dr Edward E. David, the President's Science Adviser, as a "new method of bringing flexibility to the market place", the new policy is the fruit of a study of federal patent policies carried out under the auspices of the OST by the Committee on Government Patent Policy.

The new policy, which replaces that spelt out by President Kennedy in 1963, contains the following major provisions:

- Heads of departments or agencies of the Federal government can in certain circumstances award exclusive licences to contractors, allowing them to offset risk capital in bringing an invention to the market place. The chief criterion for awarding such a licence is simply that commercialization of an invention arising from government-sponsored research "will best serve the public interest", and that the invention is unlikely to be exploited unless the company is given sufficient financial incentive.

Built into the new policy is also the provision that licences can be awarded for inventions that are the primary object of a contract. The previous patent policy had specifically prevented a contractor from gaining greater rights than a non-exclusive licence to such inventions, and the Federal Council for Science and Technology found that some agencies had misinterpreted this clause so that, for example, the Department of Health, Education and Welfare might be prevented from granting greater rights to a health invention.

Explaining the rationale behind the decision to enable departments and agencies to grant exclusive licences for the exploitation of government inventions, Mr. O. A. Neumann, executive secretary of the Committee on Government Patent Policy, said that studies have brought to light cases where inventions would not reach the market place unless a period of exclusivity was provided to the developer to recoup his private investment. Mr Neumann declined, however, to give details of such cases.

- If the Administration does decide to turn over principal or exclusive rights to an invention to a contractor, a licence to make, use or sell the invention will still be retained by the government, unless the head of the department involved determines that it would not be in the best public interest to do so.
- If the government itself decides to retain the principal or exclusive rights to an invention, it may also grant the contractor the right to a non-exclusive licence to manufacture and market the invention. But even in this case, the company's licence could later be revoked and replaced by an exclusive licence if the government decided that extra encouragement was needed to develop and market the invention.
- Finally, the new patent policy requires every department and agency to keep a close record of its licences, so that the effects of the policy can later be evaluated by the government Committee on Patent Policy. Pointing out that past government patent policies have been difficult to evaluate because of inadequately kept records of non-exclusive licences, Mr Neumann said last week "there is really no way for us to know what sort of activity we shall be getting into, and it is very difficult to see what the level of activity will eventually be".

Government departments and agencies are also divided over the question of what effect the new policy will have on their activities. NASA and the Department of Health, Education and Welfare, for example, point out that they have both in the past had the power to grant exclusive licences in exceptional circumstances, but each has only issued one or two such licences in the past few years. It seems likely, therefore, that departments and agencies will continue to allow commercial exploitation of inventions developed under government contract on a free-for-all basis as, for example, the Department of Agriculture did when a process to manufacture penicillin on a large scale was discovered under contract from the government. Exclusive rights are likely to be granted to companies only for inventions which would require large risk capital to bring them to the market place or where the market potential would be an insufficient incentive for the company to put up the development capital.

What the policy statement has accomplished, however, is to provide an explicit basis for the negotiation of government contracts which together account for some $15,000 million of federal money each year. About half of this expenditure is accounted for by the Department of Defense, which has in the past consistently assigned patent rights to the contractor when the contract was first negotiated, before any discoveries had been made. This practice has, however, come in for some attack in the past for giving away public property. What those critics will make of the new patent policy should be interesting.

DERMATOLOGY

FDA in Rash Again

by our Washington Correspondent

THE Food and Drug Administration may soon seek to extricate itself from a grave dilemma by allowing a highly toxic drug to be legally marketed for use against severe cases of psoriasis, a debilitating skin disease. The dilemma that the FDA faces is that whatever action it takes on the drug will result in strong criticism; if it allows the drug to be used against psoriasis, it will be assailed for not protecting the public against a drug that has already been shown to be highly toxic, but if it takes action against the manufacturer to prevent the drug from being sold as a dermatological preparation, it will be accused of taking out of the hands of physicians their only effective weapon against psoriasis.

The FDA has only itself to blame for its dilemma, for during the past four years it has turned a blind eye on use of the drug by dermatologists, and has taken no action against the manufacturer, Lederle Laboratories, for commercially promoting the drug for an unlicensed use. It has been fully aware of the drug's severe side effects, but has taken few steps to warn either the public or the medical profession about them.

Under the trade name 'Methotrexate' (MTX), the drug was licensed by the FDA in 1959 for use against leukaemia, but in 1963 the manufacturer notified the FDA that it was sponsoring experiments using the drug to treat psoriasis. The FDA has thus allowed the drug to have an experimental status for eight years, thereby violating its own rule that such situations should not be unduly prolonged.

Lederle Laboratories has notified the FDA of 71 different adverse side effects associated with use of MTX, ranging from disease of the kidneys, liver and blood, and ulceration, to nausea and bleeding from the nose and mouth, and the FDA is also aware that there have been at least 25 deaths associated with use of MTX to treat psoriasis. At the same time, however, some dermatologists have reported complete clearing of psoriasis symptoms from fifty per cent of patients who had the disease over as much as three-quarters of their body. Other treatments for the disease, which manifests itself as red, scaly patches which can be disabling if they cover a large area of the body, are largely ineffective.

Why cannot the FDA continue to ignore the problem as it has done for the past eight years? The chief reason is that the House Intergovernmental Relations Subcommittee which, under the chairmanship of L. H. Fountain oversees the work of the FDA, last month took the unusual step of holding public hearings on the FDA's handling of the drug. As a result, Mr Fountain has accused the agency of being "grossly remiss in not formulating and enunciating a firm but reasonable policy of enforcement", and last week he wrote to Charles C. Edwards, Commissioner of the FDA, urging him to write individual letters to physicians warning them of the hazards associated with MTX.

Fountain's letter, which was also signed by Mrs Florence Dwyer, ranking minority member on the committee, pointed out that the FDA has taken off the market drugs that are much safer than MTX, and that it would be inappropriate for the FDA to allow the drug to be marketed for treatment of psoriasis. The chief concern is that even if the FDA insists on safeguards such as strict supervision over the use of MTX, there is no guarantee that all doctors would be able to exercise the strict control that would be required, and that, in any case, adequate and well controlled studies of the efficacy and safety of the drug have not been carried out by the agency's scientists during the eight years that MTX has been on experimental trial. It is therefore argued that the FDA should warn every doctor by individual letter of the danger of using MTX to treat psoriasis, and that doctors should also be warned that continued use of the drug for unlicensed purposes could result in MTX being withdrawn from the market.

James D. Grant, Deputy Commissioner of the FDA, said in testimony before Fountain's subcommittee last month that the agency hopes soon to work out with the manufacturer an acceptable labelling for MTX which would permit its use only in severe cases of psoriasis. Such a compromise would in effect give legal sanction to the practice established during the past four years—a practice which Fountain said left him wondering whether the FDA understands its role to "enforce the law, not to debate, not to enter into agreements, not to anguish about violations but to act and terminate violations". He added that "if the FDA will not enforce the law, then the public does not need an FDA".

ALASKA

Pipeline Economics

While the Department of the Interior is busy revising its environmental impact statement on the proposal to construct an oil pipeline across the Alaskan wilderness, opposition to the plan is continuing unabated. The latest attack on the plan has come not from environmentalists, however, but from nineteen congressmen (eighteen Democratic and one Republican) who are concerned that the pipeline would exacerbate the disparity in oil prices that now exists between the west coast on the one hand and the midwest and east on the other. Led by Mr Les Aspin from Wisconsin, a noted opponent of the trans-Alaska pipeline plan, the congressmen (who all represent midwester or eastern states) have written a letter to President Nixon urging him to instruct Rogers Morton, Secretary of the Interior, not to issue permits for construction of the line until a full economic and environmental study of an alternative route through Canada has been carried out.

The nub of their argument is that present plans to pipe oil from the North Slope across Alaska to the ice-free port of Valdez, and then to ship it to the west coast for consumption, will decrease oil prices in the west and further increase the difference in oil prices between the west coast and the rest of the United States. A barrel of oil now costs 60c more on the east coast than on the west, and the letter to President Nixon suggests that the difference would be increased to about 140c if the pipeline were built. If oil were piped through Canada directly to the midwest and the east coast, however, the congressmen contend that the price differential would be wiped out. There is, however, no overriding ecological argument for rerouting the pipeline across Canada, although danger from spillage would be reduced since the Canadian route would not involve shipping, and unlike the trans-Alaska route, it is not located in an earthquake zone. The Canadian route would be about twice as long as the Alaskan route, it would cost considerably more, and it would take two or three years longer to build. In attempting to get the pipeline re-routed, its opponents, like the opponents of the SST, will therefore face considerable opposition from industrial interests. Among the signatories to the letter is Senator William Proxmire.

Short Notes

HEW Empire Attacked

Mr Paul G. Rogers, chairman of the House subcommittee on Public Health and Environment, hopes soon to introduce legislation designed to dismantle the unwieldy bureaucracy of the Department of Health, Education and Welfare. Speaking at a meeting of the American Hospital Association last week, Rogers said that health has a weak voice and leadership in the Federal Government because it has no secretary at cabinet level to argue for and coordinate the activities of the health industry, and accordingly he hopes to set up a department of health, outside the realms of HEW. Such a department, he suggested, would obviate the necessity for setting up specialist agencies such as the Conquest of Cancer Agency and the Office of Drug Abuse Control. Claiming widespread support for this proposal, Rogers pointed out that he knows of no organization that would oppose it, but even if he introduces the legislation as soon as Congress reassembles in September, it is unlikely to pass through the Congressional mill before next spring.

Professor for Life

The University of Chicago has appointed Charles L. Fefferman, this year's winner of the Prix Salem and a specialist in Fourier series, to the rank of full professor in the department of mathematics. The department has twenty-three other professors of mathematics, many of whom are better known than Fefferman, but what makes his appointment interesting is that at the age of 22, Fefferman is the youngest full professor in the history of the University of Chicago and probably of any other major university in the United States. He entered the University of Maryland at the age of 14, with the help of a special dispensation allowing him to be admitted without a high school diploma, obtained his BS degree in 1966, when he was 17, his PhD from Princeton in 1969, and was appointed assistant professor at the University of Chicago last year. Fefferman published his first paper at the age of 15, and has eight papers now in the press. His tenure of the professorship at Chicago is for life.

NEWS AND VIEWS

Detecting Underground Nuclear Explosions at Last?

IF the results of recent work in Canada are to be believed, it is possible to locate and verify explosions of more than 20 kton, fired in consolidated rocks, using seismometers in routine production. The first announcement of this achievement came at the twenty-fifth general assembly of the United Nations in December 1970, when the Canadian delegation presented a largely theoretical assessment of the feasibility capacity today for controlling a ban on underground testing of nuclear weapons. This study was based on information supplied in accordance with a resolution (2604A(XXIV)) of the general assembly in December 1969. At the Conference of the Committee on Disarmament in Geneva this summer, Canadian workers claimed, as a result of using this information in an extensive study of earthquakes and explosions, that the identification threshold for Eurasia is about 20 ktons referred to containment in consolidated rock. (To be sure, the deliberate evasion of detection is a separate question.)

Thirteen years ago this threshold of identification may well have satisfied the treaty makers, who seemed ready to negotiate an agreement on the basis of the 1958 Report of the Geneva Conference of Experts which concluded *inter alia* that some twenty to a hundred earthquakes a year would remain seismically undistinguishable from underground explosions of about 5 kton yield given a specially deployed network of control stations. Only earthquakes would be positively identified. Stations which now routinely communicate data could, the Canadian study now claims, be improved for a moderate cost such that the identification of 5–10 kton explosions would be possible with 90 per cent probability.

The criterion on which these conclusions were based is the difference between the amplitude spectra of earthquakes and explosions. The current method of measuring this difference is to apply corrections for distance, thereby normalizing the amplitudes of the P (short period) and Rayleigh (long period) waves to the magnitudes m_b and M_s respectively. Theoretical calculations presented at Beaugency in 1964 suggested that the ratio $m_b:M_s$ might be a method of identifying explosions when Carpenter (*Vesiac Report*, 4410-99-X, 119; 1966) found that the amplitudes of Rayleigh waves generated by explosions should be an order of magnitude less than those of earthquakes of equivalent body wave magnitude m_b. This result has been confirmed empirically by research at Lamont (*J. Geophys. Res.*, **71**, 4333; 1966), at UKAEA Blacknest (UKAEA *Special Report*, 46; UKAEA, 1965, and AWRE 0-67/66; HMSO, 1966) and at Ottawa (*Geophys. J. Roy. Astron. Soc.*, **17**, 1; 1969). A scientific article promised by the Canadian workers may remove the remaining uncertainties in the empirical observations, and the third part of the Cambridge series (*Geophys. J. Roy. Astron. Soc.*, **18**, 233 and 353; 1969) is expected to improve the theory.

So far as the Test Ban is concerned, however, it seems that the principal issue today is the difficulty of recording Rayleigh waves from small explosions. Compressional body waves (P) from underground explosions of 1–2 ktons have been detected and located at distances up to 80° by arrays of some twenty seismometers (AWRE 0-33/70; HMSO, 1970), but the Rayleigh waves required for identifying explosions of this size would not be recorded beyond about 10° by long period arrays of equivalent dimensions. This may be the reason why a new look is being taken at the more easily recorded body waves (P) in which interest flagged after the Novaya Zemlya underground explosions had reduced the value of the complexity discriminant (IASPEI, *Trav. Sci.*, Ser. A, Fasc. 24, 26; 1968). The Lincoln Laboratory of the Massachusetts Institute of Technology took the initiative by estimating spectral energies in selected bands of the P-wave train and found the ratio of high frequency (1.5–1.9 Hz) to low frequency (0.4–0.8 Hz) energy for earthquakes was generally lower than for explosions (IASPEI, *Trav. Sci.*, Ser. A., Fasc. 24, 25; 1968). Intuitively one might expect the seismic energy of explosions to be concentrated in the higher frequency band than for earthquakes but the discriminant worked satisfactorily in practice only for explosions in Central Asia.

On page 51 of this issue of *Nature*, Dr F. M. Anglin of the Seismology Division at the Department of Energy, Mines and Resources, Ottawa, has combined both the complexity and a modified form of the short period spectral criteria to give a satisfactory separation of earthquake and explosion samples taken from Eurasia. The methods for measuring complexity have all taken the ratio of some measure of amplitudes within the first few seconds of a short period P-wave train to the next few tens of seconds. Anglin finds the optimum condition by taking the rectified sum of the Yellowknife array elements phased to give the maximum P amplitude, and compares the first two seconds of the P signals with the following 33 seconds. In the frequency domain the principal difference from the Lincoln Laboratory procedure is to include an f_3 (Hz) term over a much wider band (0.32 Hz–5.0 Hz), and to sample the first 6 seconds of the P signal. The Lincoln Laboratory used the first 20–30 seconds.

The numbers representing these two parameters for twenty-seven underground explosions in five different areas of the Soviet Union and China, and fifty-one shallow focus earthquakes within 15° of one or other of the explosion epicentres, neatly separate the two classes independently of magnitude. Explosions with complex P-wave trains, like those detected from Novaya Zemlya, are rich enough in the higher frequencies to be included in the explosion population, and the frequency spectra of earthquakes with rather simple wave trains evidently peak at lower frequencies. There are only four samples (one explosion and three earthquakes) with magnitudes less than m_b 4.5, and because this is the magnitude range in which P-wave discriminants can make a significant contribution to the Test Ban problem, there is clearly still a long way to go. (It is important that the epicentral parameters of low yield nuclear explosions should be published.) The physical basis of both the complexity and spectral differences of seismic events is not explained, so it is impossible to predict what the result of a similar test on Nevada explosions and earthquakes would be; Lincoln Laboratory failed with these events.

OCEAN FLOOR

Standard Section

from our Geomagnetism Correspondent

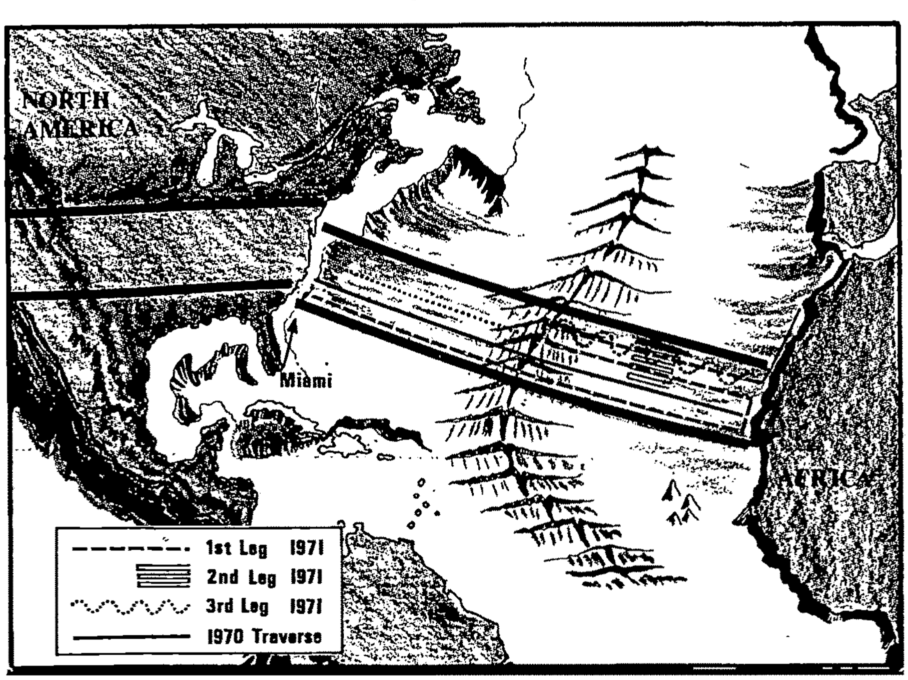
ALTHOUGH the third leg of the Trans-Atlantic Geotraverse was completed less than three months ago, some of the preliminary results have already been released by Dr Peter A. Rona, the project's chief scientist. The Trans-Atlantic Geotraverse (or TAG, in the inevitable mnemonic) was recommended in 1968 by the US National Academy of Sciences and the US Upper Mantle Committee as a desirable contribution to the International Decade of Ocean Exploration. Since it began in 1970 it has been under the direction of the National Oceanic and Atmospheric Administration which has put its own ship, the Discoverer, at the disposal of the project. According to Rona the general aim of the programme is to establish the "first standard crustal section across an ocean basin" and it certainly looks as though that will be achieved before the project is completed in 1974.

The section in question (see diagram) is a 200-mile wide, 3,500-mile long curved strip across the Atlantic from Cape Hatteras to Cap Blanc and is calculated to link points in Africa and North America which were immediately adjacent before the onset of continental drift. The western end of the traverse also links up with the Transcontinental Geophysical Survey section, the crustal section established across the United States in 1968 by means of topographic, gravitational, seismic, magnetic and rock-dating studies.

The first leg of TAG comprised three parallel tracks across the whole section. The second involved an intensive investigation of the foothills along the eastern slope of the mid-Atlantic Ridge; and, during the third, the ocean floor was sampled by dredge and corer from the mid-Atlantic Ridge to the African continental shelf. Although the project has an impeccable scientific basis in the academic sense (one of its listed aims is "a more thorough and valuable understanding of the past and present movements of the continents and rifting of the sea floor"), the emphasis is clearly on using the basic science as a guide to the assessment of the potential oil and mineral wealth of the deep oceans; and this is reflected in the first results to be announced.

Thus Rona reports that "extremely heavy" encrustations of manganese ore (which also contains copper, nickel and cobalt) have been found on exposed rocks in regions where Earth movements have caused fractures in the sea bed; and these deposits are believed to be thicker and more extensive than the better known manganese nodules found in other areas in recent years. Also under investigation by the TAG scientists—although no actual results have so far been given—is the relation between the rifting of a continent and the formation of heavy metals such as gold and platinum. Heavy metal ores are a feature of the Red Sea, a region thought to be in the early stages of rifting; and it is thus possible that the volcanic activity accompanying the formation of the mid-Atlantic Ridge may have left heavy metal deposits in the deep Atlantic beyond the continental shelves.

But of perhaps even greater significance are the large domes which have been found in the TAG section off north-west Africa and which resemble the oil-bearing salt domes in the Gulf of Mexico. The Atlantic domes which lie in 15,000–20,000 feet of water and some of which lie at least 800 miles off the African coast would, if their salt content is confirmed, be the first salt domes to be reported in the deep ocean and, as such, would represent the first indication of potentially significant marine oil resources beyond the continental shelves. The hypothesis which Rona and his colleagues are trying to test is that during its early development the Atlantic must have been a body of water almost completely surrounded by land and thus in which evaporation exceeded inflow. Under these conditions salinity would increase and salt would be precipitated, forming layers (and subsequently domes) into which would settle oil-forming plant and fish remains. As the Atlantic opened further, some of these deposits would be left in the deep ocean floor and not only on the continental shelf. So far, however, the validity of this hypothesis has not been confirmed.



ASTRONOMY

Universal Distance

from a Correspondent

How big is the universe? This was the theme of a conference on the galaxy and the distance scale held at the Royal Greenwich Observatory, Herstmonceux, from August 17 to 20 in honour of the Astronomer Royal, Sir Richard Woolley, who retires at the end of 1971.

The conference covered the whole range of distance determinations, from nearby stars to galaxies and quasars. Distances of galaxies are found by a series of intermediate steps involving galactic clusters, cepheid variables, ionized hydrogen regions and galaxies themselves as standard beacons; the latest results reported by Dr A. R. Sandage (Hale Observatories, Pasadena) give a Hubble time (time since the "big bang" if deceleration is neglected) of 18×10^9 years, exactly ten times the value estimated by Hubble in 1936, and a deceleration parameter $q_0=0.95\pm0.4$. This permits a universe that will either go on expanding indefinitely or fall back and oscillate, but probably excludes the steady-state theory ($q_0=-1$). The actual age of the universe then comes out to be about 13×10^9 years, which compares very favourably with the age of $(10\pm3)\times10^9$ years estimated for old stars in globular clusters on the basis of the theory of stellar evolution. The uniformity of the relationship between period, luminosity and colour of cepheid variables in different galaxies makes these estimates seem more firmly based than earlier ones.

Intermediate steps in the measuring process involve the distances of clusters and variable stars, corrections for absorption of light in interstellar space, the distance between the Earth and the centre of our galaxy and the distances to our two nearest extragalactic neighbours, the Magellanic Clouds. The distances of clusters depend on fitting their "zero-age main sequence" in the temperature-luminosity diagram to that of the Hyades cluster which is well determined by the moving-cluster method and confirmed—as was shown by Dr O. J. Eggen (Mount Stromlo Observatory, Canberra)—by entirely independent measurements of the temperatures, magnitudes and trigonometric parallaxes of nearby stars resembling the Hyades in age, motions and chemical composition. The absorption of light in interstellar space immediately surrounding our solar system was shown by Dr B. Strömgren (Copenhagen University) to be almost entirely concentrated in discrete small clouds or large cloud complexes, with almost no continuous distribution of dark matter between the clouds.

Going out to distances more comparable to the size of our galaxy, Sir Richard Woolley described the determination of luminosities of pulsating variables by the Baade-Wesselink method of comparing actual changes in radius deduced from velocity variations with the relative change deduced from variations in brightness and surface temperature. In combination with the theory of pulsation, this method leads to quite low masses for many variables which in turn suggests that they could have lost mass in the course of their evolution. Dr W. Becker (Basle University) described a procedure for building up a contour map of star density in the disk and halo of our galaxy by photometry in red, green and ultraviolet bands of the spectrum which enables faint stars of different luminosity and chemical composition to be sorted out. Dr A. Toomre (Massachusetts Institute of Technology) showed that the distortion of the central plane of our galaxy could be explained by tidal action of the Magellanic Clouds provided that the Earth's distance from the centre of our galaxy does not exceed 8 kiloparsecs (compared with the round figure of 10 kiloparsecs adopted by the International Astronomical Union some years ago). But an attempt to improve galactic constants by studying proper motions was found by Dr S. V. M. Clube (Royal Greenwich Observatory) to lead to inconclusive results.

Are the redshifts of quasars of cosmological origin, indicating enormous distances, or are they an intrinsic effect due to other causes? Arguments on each side were reviewed by Dr M. Schmidt (California Institute of Technology), who showed that the hypothesis of an intrinsic origin would require a revision of present-day concepts in physics, but that the cosmological hypothesis is not fatally in conflict with any results obtained to date.

X-RAY ASTRONOMY

Model for Sco X-1

by our Cosmology Correspondent

SINCE the discovery that Sco X-1 is a triple radio source with some features like those of a pulseless pulsar, there has been speculation that the source might indeed belong to the same family as pulsars (see *Nature Physical Science*, **229**, 218; 1971). K. Davidson, F. Pacini and E. E. Salpeter have now published a detailed model for the thermal X-ray emission from Sco X-1 in terms of a hot gaseous region surrounding a rotating neutron star (*Astrophys. J.*, **168**, 45; 1971). Although this model was developed before the recent flurry of activity which has resulted in the discovery of periodic variations in Centaurus X-3 and Cygnus X-1, these discoveries can, on the face of it, only add to the interest in models such as that of Davidson *et al.*

With all models of Sco X-1, the fundamental problem is the generation of thermal bremsstrahlung—the source has maintained a temperature of roughly 5×10^7 K for a decade, and it has been widely accepted that the basic energy source must be gravitational, with accretion of gas onto a white dwarf releasing energy as proposed by Prendergast and Burbidge in 1968. But the difficulty of explaining the detailed flaring and flickering of Sco X-1 at both optical and X-ray frequencies, together with the presence of intermittent periodic and quasi-periodic structure in the light curves from the source, makes it desirable that other models should also be studied. Davidson, Pacini and Salpeter have looked at models in which the energy source is a rotating neutron star, the inspiration for this stemming from the apparent success of the rotating neutron star model in explaining the energy generation mechanism operating in pulsars.

The model which is most successful has a dense shell of gas surrounding the central pulsar. Supported by particular and electromagnetic radiation far beyond the speed of light circle, at a distance of roughly 10^9 cm, this cocoon is heated to the observed temperature by the radiation it absorbs. For Sco X-1, the observations require that such a shell must be quite thick, the density in the line of sight being several g cm^{-2} so that the pulsar frequency fields do not penetrate the cocoon. Plausible values for the efficiency of the heating mechanism and the mass of the underlying star suggest a pulsar period of 3 ms and a gas cloud radius of 1.5×10^9 cm. But the surface field required is only 5×10^9 G,

Infrared Variations in Seyfert Galaxies?

ALTHOUGH measurements of the infrared emission of the Seyfert galaxy NGC4151 at 11 μm do not yield any evidence of significant flux changes with time, the possibility that some flux changes have occurred cannot be ruled out. That is the principal conclusion reached by Stein and Gillett in next Monday's issue of *Nature Physical Science*.

These results are of particular interest because of their importance for the radiation mechanisms at infrared wavelengths greater than about 10 μm. One model of Seyfert galaxies, for example, proposes that there is a central luminous source of short wavelength radiation surrounded by a cloud of particles that radiate at infrared wavelengths. This model would be untenable if there were fluctuations on a time scale of less than about a year. Variations of the order of a day would also place serious constraints on models involving non-thermal infrared sources.

Quite a large amount of evidence has been accumulated for time variations of the visible and radiofrequency flux from the nuclei of Seyfert galaxies and possible variations have also been reported at the near infrared wavelengths of about 2 to 3 μm; Stein and Gillett have now extended these measurements to 11 μm with photometric measurements of NGC4151 made during the two years up to June 1971.

They have found two pieces of evidence that seem to suggest variations on a time scale of less than a month. In both cases the three standard deviation upper limit of one measurement was much lower than the lower limit of the flux a few days later. But Stein and Gillett are quick to point out that deductions from this can be misleading, and they apply several statistical checks. They find, for example, that the standard deviation of the distribution of their twenty-nine measurements is only slightly greater than the average standard deviation of the individual measurements whereas, if variations had occurred, larger differences would be expected. The numbers of measurements lying within one, two and three standard deviations of the mean of the twenty-nine measurements are also close to the numbers expected if there is no variation. Similar conclusions were reached after analysis of measurements on a comparison star (γ U Ma).

which is much lower than the surface fields required for pulsars and allows the extremely rapid rotation to persist for millions of years.

Typical time scales which Davidson *et al.* expect to be associated with the motions of the components of their model range from the pulsar period, roughly 0.003 s, to the time scale for dynamic equilibrium, roughly 3,000 s. The orbital period of the gas is 30 s, and its cooling time is roughly 0.3 s, so that it must indeed be continuously excited for the system to be stable.

Most of the objections to this model are certainly no more severe than those which apply to other models for Sco X-1. Indeed, with the exception of the rather low magnetic field, the estimated parameters agree well with observations of this and other sources, and the cocoon seems a suitable source of erratic variations of the kind detected. Two crucial tests seem relevant. One or two such objects could be detected without a drastic re-thinking of the theory, but many more sources in the Sco X-1 mould would rapidly become a surfeit. And if Sco X-1 itself does show a continuation of the decline in activity and, possibly, temperature which has been hinted at by some recent observations, then it would seem to be too short lived for the Davidson *et al.* model—this would certainly be a new development, because the downfall of most models of the object so far has been their implausibly short time scales compared with the observed lifetime of Sco X-1.

MINICELLS

Exploiting Cytochalasin

from our Cell Biology Correspondent

ALTHOUGH minicells, small enucleate *Escherichia coli*, have been used occasionally by molecular biologists, it seems safe to say that they became available too late in the game. Many questions, which might with comparative ease have been answered by experiments with minicells, had already been solved by hard work and ingenuity with nucleate *E. coli*. But animal virologists look to be more fortunate for it seems, if the experiments of Prescott, Kates and Kirkpatrick (*J. Mol. Biol.*, **59**, 505; 1971) are anything to go by, that enucleate cells obtained by exposing nucleate cells in culture to cytochalasin B can be exploited to answer many outstanding questions.

Prescott and his colleagues have used enucleate L cells produced in this way to prove quite unambiguously that the uncoating and replication of vaccinia virus does not depend on the presence of a host cell nucleus. After exposing L cells to cytochalasin B, and in some experiments to actinomycin D as well to inhibit any RNA synthesis that the cytochalasin B might induce, and then washing the cultures and incubating them for 2 h in medium they added vaccinia virus and followed the fate of the infected nucleate and enucleate cells by light microscopy and autoradiography. Typical "factories" synthesizing vaccinia DNA develop in the enucleate cells and so the suggestion, originally made by Joklik in 1964, that the uncoating of vaccinia virus depends on a function coded by a host cell gene and activated by infection, has been neatly eliminated.

Joklik's suggestion stemmed, of course, from the finding that after the removal of the lipoprotein outer coat of vaccinia virus, the second step in its uncoating, the disruption of the inner "core" protein coat is specifically blocked by inhibitors of RNA and protein synthesis. This indicated that the synthesis and translation of messenger RNA was essential for the second stage of uncoating and in 1964 it seemed quite plausible that the gene(s) in question might well be cellular rather than viral. By 1967, however, Kates and McAuslan had shown that vaccinia cores with their protein coat intact can make and release messenger and Joklik's idea was beginning to look unnecessarily complex. Prescott's results are not altogether unexpected therefore and the chief interest in what he and his colleagues have to say lies in the method they have used.

Clearly, hypotheses which implicate directly the host genome in the replication of other animal viruses might be put to the test with enucleate cells. It would, for example, be interesting to know how far the replication of RNA tumour viruses proceeds in such cells. For that might reveal whether or not the stable association between a DNA provirus, which, as Hatanaka *et al.* have just shown (*Proc. US Nat. Acad. Sci.*, **68**, 1844; 1971), is probably made in the cytoplasm, and the host genome is essential for replication of these viruses.

Transfer RNA Precursor Sequenced

IN next Wednesday's *Nature New Biology*, Altman and Smith describe their latest investigations of the tyrosine transfer RNA precursor molecule of *Escherichia coli* and its maturation into tyrosine transfer RNA; their work is a remarkable example of the pitch of sophistication which has been reached in analyses of bacteria.

As Altman recently reported in *Nature New Biology* (**229**, 19; 1971) transfer RNAs, like ribosomal and probably messenger RNAs, are transcribed as part of a larger precursor molecule which is matured by cleavage. What Altman and Smith have now done is analyse the base sequence of the precursor of a tyrosine transfer RNA, prove that mutations which alter the amount of the mature RNA produced are located in a region of the precursor close to the cleavage point and detect a nucleolytic activity in extracts of *E. coli* which *in vitro* matures the precursor.

Obtaining strains which accumulate precursor involved a series of elegant genetic manipulations; with these achieved Altman and Smith obtained enough precursor to analyse its base sequence and they found several striking features. First, bases which, in mature transfer RNA, are modified are, in the precursor, unmodified. Second, it seems that the CCA sequence at the 3′ terminal end of the mature molecule is present in the precursor, contrary perhaps to expectation. Third, many of the oligonucleotides obtained after partial digestion of the precursor with T_1 ribonuclease correspond to those obtained after partial digestion of the mature molecule. This situation suggests that even in the precursor the secondary structure of the mature tRNA sequence has a clover leaf secondary structure. Finally, the 5′ terminal residue of the precursor is pppGp, which suggests that transcription *in vivo* as *in vitro* is initiated with a 5′ triphosphate purine nucleotide.

Altman and Smith then sequenced the precursor specified by a mutated tyrosine transfer RNA gene, which *in vivo* matures unusually rapidly. To do this, of course, they had to introduce other mutations which caused this precursor to accumulate. The sequence revealed that the mutation which leads to a rapidly maturing precursor changes a base four nucleotides removed from the cleavage point. Moreover, other mutations which cause the production of reduced amounts of mature transfer RNA but no accumulation of precursor also change bases close to the cleavage point. For these reasons Altman and Smith suggest that both the base sequence and the secondary structure at the cleavage point probably affect the rate and the precise point of cleavage and they propose models of the structure of the precursor which might account for these factors.

Finally, they have succeeded in detecting in extracts of *E. coli* a nucleolytic activity which *in vitro* cleaves the precursor at the correct point and yields a transfer RNA fragment with the same 5′ terminus as transfer RNA matured *in vivo*. This finding proves that modification of certain bases in the transfer RNA segment of the precursor is not essential for proper maturation. Indeed, modification may well occur *in vivo* after the precursor has been cleaved.

HAEMOGLOBIN

Monomers Monitored

from our Molecular Biology Correspondent

THE nature and strength of subunit interactions in proteins has an intimate bearing on the interconversion between states of high and low ligand affinity, which lies at the heart of control of activity. Here, as so often, haemoglobin is the archetype. That the tetramer is in dissociation equilibrium with dimer was established in the very dawn of protein history by the old masters, Svedberg and Pedersen. More recently debate has centred on whether, at sufficiently low concentration, the dimer will in turn give rise to monomer. The general view was that at the lowest observable protein concentrations the monomer remains below the level of detectability. Schachman and Edelstein, on the other hand, reported substantial dissociation into monomers, on the basis of sedimentation equilibrium measurements with scanner optics. This conclusion has now been repudiated by Kellett and Schachman (*J. Mol. Biol.*, **59**, 387; 1971).

Scanner optics for this system offer the advantage that by operating at the wavelength of the very intense Soret absorption band of the haemoglobin, measurements can be made at concentrations as low as about 10^{-8} M in subunits. Unfortunately, oxyhaemoglobin in such dilute solution is prone to oxidize to the ferric form, which then denatures, with irreversible formation of monomeric chains. This seems to have been the cause of the previous error. Kellett and Schachman's re-evaluation was made possible by the remarkable observation that methaemoglobin formation is inhibited by the presence of EDTA, which one can only suppose to function by sequestering traces of heavy metals that would otherwise catalyse the oxidation reaction. At all events, under these conditions the equilibrium distribution in the ultracentrifuge reveals that only oxyhaemoglobin dimer is present, and the same is true of other stable derivatives, such as carboxyhaemoglobin and methaemoglobin cyanide and azide. It may be noted that Bucci (*ibid.*, **55**, 401; 1971) also recently concluded that at concentrations down to 10^{-8} M, oxyhaemoglobin gave rise to no significant amount of monomer, for a complement fixation technique, sensitive at such low levels, revealed the absence of any hybridization between two different molecular species, such as would occur were there a finite degree of dissociation beyond the symmetrical dimer ($\alpha\beta$) stage.

In an accompanying article, Kellett (*ibid.*, **59**, 401; 1971) tackles the much more demanding problem of dissociation of oxy and deoxyhaemoglobin under the influence of high salt concentrations. The difficulties are both experimental, in regard to the anaerobic manipulation of the deoxygenated solutions, and theoretical, in terms of the thermodynamics of the three-component system of protein, water and salt. Kellett has devised an analytical procedure which yields the dissociation constant for the dimer-tetramer equilibrium in terms of a buoyant weight, extracted directly from the sedimentation distribution. The upshot is that whereas the dissociation of oxyhaemoglobin to dimers (though not monomers) is strongly promoted by salt, deoxyhaemoglobin remains tetrameric even at the lowest observable concentrations in 2 M sodium chloride or iodide. Qualitatively the finding of such resistance of the unliganded protein to dissociation is not new, but Kellett's results make it clear that its dissociation constant is not less than three orders of magnitude lower in 2 M sodium chloride than that of oxyhaemoglobin. Evidently then, resistance to dissociation is a feature of the "constrained" (low-affinity) structural state. This has a number of implications in relation to functional schemes that have been propounded, and also explains the apparently anomalous failure of the cooperativity (Hill constant) to diminish in high salt, when, it was thought, the protein was dissociated to dimers.

It is interesting to find that some putative evidence for haemoglobin monomers in a quite different context has now been annihilated. The haemoglobin-binding protein of serum, haptoglobin, attaches to haemoglobin at sites on the α-chains. Nagel and Gibson found that when haptoglobin was partly saturated with haemoglobin α-chains, β-chains were taken up, and this process occurred at a faster rate than when whole haemoglobin was added in place of β-chains. This result was put down to a slow dissociation of the tetramer, by way of the known $\alpha\beta$ dimers, to single β-chains, which then rapidly associated with the haptoglobin-bound α-chains. Boyd, Smith and Andrews (*Canad. J. Biochem.*, **49**, 891; 1971) prepared the α-chain-haptoglobin complex, and added to it an excess of mouse haemoglobin. By gel filtration they then separated out of the mixture, first, a haemoglobin-haptoglobin stoichiometric complex, second, mouse haemoglobin, and, finally, human α-chains. Evidently then, the initially bound α-chains are displaced. Now it is known that mouse and human haemoglobins hybridize satisfactorily. Boyd *et al.* conclude therefore that monomers do

Supermassive Rotors and Active Galactic Nuclei

A LONG standing model for quasars and active galaxies postulates the presence of supermassive differentially rotating stars, supported by radiation pressure, at the centres of these objects. In spite of other suggestions, including the possibility of pulsar-like emission from a supermassive rotating object, this relatively simple model remains a likely explanation for the energy source in quasars and galaxies. But the model is only superficially simple—although it is clear from the most naive calculations that a supermassive rotating disk satisfies the broad requirements of the primary energy supply in highly energetic sources, quantitative calculations concerning the evolution of such disks remain inadequate. It is only within the past two years that it has been shown that disks of this kind are unstable against fragmentation, and although this complicates further calculations the prospect raises some interesting conjectures regarding the ultimate fate of the disks. E. E. Salpeter, of Cornell University, has now provided an outline of the successive fragmentations which should accompany the slow evolution of a supermassive star. This approach, presented in next Monday's *Nature Physical Science*, raises several questions which point the way for further development of the model.

It seems that, so long as the disk is radiation dominated, fragmentation must occur. This process will be repeated in the subdisks formed, until small objects supported by hydrodynamic forces are formed. Because the descendants of the original disk will form a hierarchical grouping after several fragmentations, radiation escaping from the system will suffer successive redshifts as it leaves first the subgroup from which it originates, then the group of subgroups in which that subgroup lies, and so on.

One source of electromagnetic radiation could be pulsar-like activity, which would occur just before the fragmentation of any disk which carries a magnetic field.

The major difficulties in extrapolating this simple picture to more realistic models concern differential rotation and the detailed nature of the gravitational and pulsar radiation emitted. Gravitational radiation, for example, might result in selective changes in the orbits of the fragments until a stable, symmetric pattern with no gravitational radiation is formed.

not enter into the scheme at all. Whereas β-chains can add directly to the complex, the reactive species in haemoglobin is the $\alpha\beta$ dimer, and the slow step is then the dissociation of each α-chain from the haptoglobin to allow an $\alpha\beta$ unit to bind in its stead.

UPPER MANTLE

Tasman Conductivity

from our Geomagnetism Correspondent

THE Tasman Geosyncline, which lies along the southern part of the east coast of Australia, is a long structure generally some 200–300 km wide and includes two major topographic features, the Australian Alps and the Main Dividing Range, as well as the three major cities of Canberra, Melbourne and Sydney. Geologically it comprises folded and metamorphosed rock belts of Ordovician to mid-Devonian age and includes the major granite batholith which forms Mount Kosciusko, at 2,219 m the highest point of the Australian continent. Seismic refraction studies have shown that the crustal rocks beneath Canberra are about 40 km thick but thin to about half of that in the coastal region. The eastern boundary of the geosyncline is not particularly clear although seismicity extends to the continental shelf. The western boundary, on the other hand, is rather different; seismological studies have indicated quite a clear boundary to the current tectonically active belt. Little, however, is known about the region immediately to the west of the geosyncline in spite of its proximity to the three principal Australian cities. Outcrops are poor there and the only major structure mapped, and that superficially, is a sedimentary basin.

To learn something about the behaviour of the upper mantle, both beneath the geosyncline and to the west of it, Tammemagi and Lilley (*Geophys. J.*, **22**, 505; 1971) have made four magnetotelluric soundings at 150 km intervals roughly along the latitude of Canberra—at Moruya on the east coast, Spring Valley near Canberra almost on the crest of the belt, Wagga Wagga slightly to the west of the geosyncline and Griffith well to the west. The magnetotelluric method itself is not new, although in this case automatic equipment was operated at each site for at least four weeks, a rather longer than usual period, to ensure that enough events were recorded. In spite of the long history of the method only a handful of magnetotelluric measurements have ever been made in Australia and none at all in what could be regarded as Australia's best known geological region.

Three events or periods of activity, including at least one magnetic storm, were frequency analysed for each site and for signals in the period range 10^3 to 10^4; and the usual curves of apparent resistivity (of the upper mantle) were constructed. As is well known, the interpretation of magnetotelluric data is frequently hampered by the inherent ambiguities, especially where the frequency range is limited and where the curves of apparent resistivity show anisotropy. In this particular work, three of the four stations were troubled by anisotropy. At Moruya, on the east coast, ocean-induced anisotropy is clearly present. The data are most consistent with a two-layer conductivity model although because of the anisotropy a large number of detailed models within this classification are possible. At Wagga Wagga and Griffith the situations are similar except that three-layer models are more appropriate. But at Spring Valley, close to the crest of the geosyncline, there is no anisotropy. A two-layer conductivity model is again most appropriate here although a range of electrical conductivity structures is possible.

But although anisotropy and the limited frequency range have prevented Tammemagi and Lilley from making detailed conductivity models, one important fact has emerged from the data —this is that in the depth range 100–300 km the electrical conductivity under the stations Moruya and Spring Valley is an order of magnitude higher than that under Wagga Wagga and Griffith.

In other words, the conductivity is higher under the Tasman Geosyncline than under the region to the west of it. In view of the correlation between electrical conductivity and heat flow discovered in Utah and Colorado by Reitzel *et al.* (*Geophys. J.*, **19**, 213; 1970), Tammemagi and Lilley interpret this as a temperature difference in the upper mantle between the two regions. Using the relationships presented by Tozer (*J. Geomagn. Geoelect.*, **22**, 35; 1970), they calculate that at a depth of about 200 km the temperature difference should be about 200° C; but whatever the precise figures, the existence of a

Helping Human Adenovirus to Replicate

SEVERAL human adenoviruses infect only abortively African green monkey kidney cells—the virus particles penetrate these cells and are uncoated; viral RNA is made, the viral genome replicates and at least some viral proteins are synthesized, but very few progeny virus particles are produced. In these monkey cells it seems that either some crucial viral proteins are not synthesized or the transport of the viral proteins from the cytoplasm where they are made to the nucleus where progeny virus particles are assembled is blocked. By coinfecting the cells with simian virus 40, however, these blocks are removed and the yield of adenovirus is greatly increased. In other words, SV40 provides some helper function which permits human adenoviruses to complete their replication in non-permissive monkey cells. In next Wednesday's *Nature New Biology*, Henry, Slifkin and Merkow report experiments which shed some light on this intriguing phenomenon.

Henry *et al.* infected with human adenovirus 2 coverslip cultures of non-permissive African green monkey kidney cells and permissive VERO and HeLa cells, which support the complete replication of this virus. Some of the monkey cell cultures were also coinfected with SV40 either immediately or within 24 h and 5-fluorodeoxyuridine (FUdR) was added to some of the coinfected cultures. This drug blocks the synthesis of "late" SV40 proteins but does not impair the SV40 helper function(s). At 24 or 45 h after infection 2 min pulses of labelled amino-acid were fed to the cultures which were then chased with cold medium. The synthesis and transport of protein made during the pulse could then be measured by autoradiography.

In brief Henry *et al.* found, using an immunological precipitation assay to differentiate between viral and host proteins, that some 60–70 per cent of the viral protein made in permissive cells is transported into the cell nuclei. In the monkey cells infected by adenovirus 2 alone only about 20 to 30 per cent of the protein labelled during the pulse is in the nucleus some 2 h later, the remainder is still in the cytoplasm concentrated about the periphery of the nucleus. By contrast, in monkey cells coinfected with SV40 and exposed to FUdR about 50 per cent of the adenovirus protein is transported to the nucleus. Further, the amount of viral protein made in the coinfected cells is significantly greater than the amount made by the cells infected with adenovirus alone.

It seems therefore that some SV40 gene product(s) not only enhances the synthesis of adenovirus proteins but also promotes the transport of these proteins into the nucleus where they are assembled into capsomeres and capsids. It is probably this second helper function which is chiefly responsible for increasing the yield of progeny virus particles; its molecular basis, needless to say, awaits elucidation.

temperature contrast is presumably reflected by, either as cause or effect, the tectonic activity within the geosynclinal region.

The possible presence of temperature variations naturally raises questions about the heat flow in the area although, unfortunately, very few measurements have been made. There is, however, a published heat flow value of 2.0–2.2 μcal cm^{-2} s^{-1} at Spring Valley and one of 1.1–1.2 μcal cm^{-2} s^{-1} at Moruya which suggest that towards the middle of the geosyncline at least the heat flow is higher than average in keeping with the enhanced mantle temperature. By the same token, heat flow to the west should be lower, though not necessarily lower than the world average. The only heat flow determinations to the west are several hundred kilometres away at Broken Hill which is itself in a tectonic region, the Adelaide Geosyncline. Tammemagi and Lilley thus predict a heat flow trough between the two geosynclines and, should such a trough be proved, look forward to confirmation of their interpretation of the magnetotelluric data.

CENTRAL NERVOUS SYSTEM

Useful Brain Cells

from our Cell Biology Correspondent

BIOCHEMISTS debating whether or not to take the plunge and tackle some of the biochemical problems posed by the development and differentiation of the central nervous system should be encouraged by what Seeds has to say in the latest issue of the *Proceedings of the US National Academy of Sciences* (**68**, 1858; 1971). For he has shown that dissociated mouse embryo brain cells, when put in rotation cultures, form themselves into aggregates which continue to undergo at least some of the biochemical changes that occur during the normal postnatal development of the intact mouse brain.

Seeds chose to follow the activity in his aggregates of three enzymes, choline acetyltransferase, acetylcholinesterase and glutamate decarboxylase, which are associated with the process of nerve transmission and which greatly increase in activity in the mouse brain during the first three to four weeks of postnatal life: the central nervous system of mice is unusually poorly developed at birth and both the formation of synapses and the growth of dendrites as well as biochemical development occur after birth. Seeds finds that the time course and pattern of increase in the activity of choline acetyltransferase and acetylcholinesterase in intact brains and in the aggregates of embryonic brain cells in culture are encouragingly similar.

Moreover, morphological differentiation also occurs in the aggregates; Seeds mentions, for example, the presence of numerous synapses. Although nobody suggests that these aggregates can be used to solve all the questions posed by the development of the central nervous sys'tem they at least offer a most promising starting point.

Brain cells also have attractions for biochemists interested in cytoplasmic microtubules, and Bryan and Wilson (*ibid.*, 1762) report that these organelles in embryonic chick brain cells are polymers of two species of protein not one. Using colchicine as a label, several groups have isolated microtubule subunits from a variety of different cells. The best characterized of these, isolated from adult human brain, appears to be a dimeric molecule comprising two polypeptide chains weighing about 55,000 to 60,000 daltons, and it has generally been assumed that the two polypeptides in each dimer are identical. Bryan and Wilson, however, find that the two polypeptides of the dimer protein of chick brain microtubules can be separated by polyacrylamide gel electrophoresis after they have been reduced and acetylated. Furthermore, although these two polypeptides have the same molecular weight, about 55,000, they differ significantly in their content of six amino-acids.

From this and similar studies of microtubules from other sources Bryan and Wilson conclude that the basic subunit of these organelles is an $\alpha\beta$ dimer, rather than an $\alpha\alpha$ dimer or a mixture of $\alpha\alpha$ and $\beta\beta$ dimers.

CHEMOSYSTEMATICS

New Committee

A JOINT Committee on Chemotaxonomy has recently been formed by the International Union of Pure and Applied Chemistry (IUPAC) and the International Association for Plant Taxonomy (IAPT) to look into all aspects of the organization of international collaboration in chemosystematics. The committee invites comments from interested persons; these should be sent to the chairman (Dr W. F. Grant, Genetics Laboratory, Macdonald Campus of McGill University, Ste. Anne de Bellevue 800, Quebec, Canada) or to the secretary (Dr T. Swain, Royal Botanic Gardens, Kew, Richmond, Surrey, England).

Polyadenine and Haemoglobin Messenger

LAST year, Lim and Canellakis (*Nature*, **227**, 710; 1970) discovered tracts of polyadenine, some fifty to seventy bases long, in the ribonuclease digests of purified rabbit globin messenger RNA. Since then similar tracts of poly A have been detected in RNA fractions, isolated from the polysomes of HeLa and ascites cells, which are also presumably messengers. It seems therefore that the presence of sequences rich in adenine may be a general feature of many, perhaps even all, eukaryotic messengers. Because of their restricted sequences it has been generally assumed that these tracts are not translated but occur on either, or on one side of the coding sequence in the messenger, and in *Nature New Biology* next Wednesday Burr and Lingrel report direct evidence that this is the case.

After labelling the 3′ terminal residues of rabbit globin messenger RNAs with tritiated borohydride they digested the molecules with either T_1 or pancreatic ribonucleases and isolated the 3′ terminal fragments. After T_1 digestion these fragments elute from 'Sephadex' columns in the region at which oligonucleotides with eight phosphate residues appear. The terminal base of this fragment is adenine. The 3′ terminal fragments obtained after pancreatic ribonuclease digestion, which cannot contain pyrimidines, are five and six bases long and, because the first guanine residue cannot be within nine bases of this terminus, Burr and Lingrel conclude that these messengers have at their 3′ termini a tract of five or six adenine residues and from the known amino-acid sequences of the rabbit globins it is clear that these bases are not translated.

The sequences Burr and Lingrel have analysed are considerably shorter than those detected by Lim and Canellakis, and there are several possible explanations of this difference. Much longer poly A sequences may exist at the 5′ ends of these molecules; the short sequence Burr and Lingrel have determined may be part of a much longer adenine rich tract or the poly A tracts may be labile and partially lost either during the extraction of the messenger or indeed *in vivo* as the molecules age. Needless to say, the function of poly A in eukaryotic messengers is as yet a matter of speculation and, as anybody who reads what Burr and Lingrel have to say will realize, there is no shortage of ideas.

The Doomsday Syndrome

JOHN MADDOX

THE past few years have been quite remarkable for the way in which there has flourished a rich vein of commentary on the place that science and technology occupy and should occupy in the modern world and for the way in which the underlying theme of this commentary has tended to be that science and technology will quickly bring society to its knees. Even quite short memories are sufficient to show that this development flies in the face of the view of the social function of science and technology that was current and commonly accepted as recently as twenty years ago. Then, and for the best part of a century before, it was supposed that social progress must rest on technical progress of some kind or another. The great philanthropists of the nineteenth century, for example, were constantly linking their schemes for liberating people from unpalatable and degrading occupations with the hope that mechanical alternatives would be found for jobs of work that were manifestly unsuitable for people. They were buoyed up by the encouragement of the nineteenth century liberals and by the legacy of the earlier utopians—people like Godwin, for example—who took the view that there would be no limit to the achievements of the human spirit so long as people could be liberated from the need for drudgery so as to keep alive and from the restraints of the environment in which they found themselves and which was, almost by definition, hostile. It is hard to imagine a more complete contrast than that between the way in which technical developments used to engender optimism and the way in which the prospect of technical innovation has now become a kind of threat.

The signs of this new attitude are now plain to see. First of all, the commentators are conspicuous and what they have to say is arresting. Several arguments have been used in the past few months to heighten the sense of impending disaster. The rapid growth of the world's population is, for example, one of the most common. And, of course, it is by now well known that the population of the world cannot continue to grow at the present pace for decade after decade. On present estimates, the world's population probably falls only little short of 4,000 million, and so many of the people now alive are either children or still in the child-bearing age group that it seems unlikely that contraceptive devices, however fully and ardently employed, will allow the world's population to stabilize at less than 7,000 million. This population should be reached by the turn of the century. It goes without saying that the most spectacular growth will be in the countries still at an early stage of their economic development so that, by the year 2000, countries such as Brazil and Indonesia will be roughly comparable in the size of their populations with the United States and the Soviet Union.

The prospect of this pattern of growth has apparently caused great consternation in the past few years. The most vociferous prophet has been Dr Paul Ehrlich, who has held quite openly that what he calls "the population bomb" must spell disaster for society at large, not merely for those unfortunate communities where the pace of growth is greatest. And what kind of disaster? Dr Ehrlich says quite categorically in his best-known book that the world will run out of food—that the mid-seventies will be times when famine is rife and when tens of millions of people will die each year of starvation. This view, itself an echo of the doctrines which Malthus put forward in the earlier versions of his distinguished tract on population, has been taken up by all kinds of commentators, from people like Lord Caradon to a host of popularizers. In the circumstances, it seems almost an indecent question to ask whether disaster is as near as all this talk suggests.

In the first place, however, it is a surprising fact that the population of the world has grown less quickly than its production of food. The Food and Agriculture Organization of the United Nations, in its time one of the most fervent beaters of the calamity drum, has kept statistics of food and population going back to the early nineteen thirties. The remarkable feature of these statistics is the way in which food and population appear to march hand in hand. Although there are obviously ups and downs in the statistics of food production, chiefly because of fluctuations of climate from one year to another, the production of food per head of population has actually increased by five per cent between the late thirties and the late sixties. And now, as everybody knows, many developing countries are faced with the prospect not of famine but of the social and economic problems of marketing harvests of cereals which so far exceed the past performances of peasant farmers that it is necessary quickly to develop the commercial machinery long familiar in the agriculture of nations in which subsistence agriculture has long since disappeared. In other words, whatever the prophets of doom may say, it does seem that famine will not be the most obvious cause of calamity in the next decade. On this point, it appears, the doomsday view seems entirely inappropriate.

To say all this does not imply, of course, that the pace of growth of the world's population brings no unfortunate or unforeseen consequences, or that nothing needs to be done about it. It is, however, important that these problems should be seen in their historical perspective. Students of population are impressed with the way in which it seems to have taken the human race from the beginning of its evolution two million years ago to the beginning of the nineteenth century to reach 1,000 million, a further century to add a second thousand million to the total roster and merely half a century since then to double the population of the world. On the face of things, this is much more than exponential growth—the time constant is continually decreasing. Yet there are good reasons for thinking that the growth of a human population is much more complicated and subtle than the growth of a population of bacteria in a set of Petri dishes.

In Britain, for example, the mediaeval population was kept in check by a succession of infectious diseases, from plague to influenza. The agricultural revolution in the eighteenth century so increased the productivity of the land that the population was able to grow quite quickly, and there is plenty of evidence that from the second half of the eighteenth century on, the birth rate in Britain was much less than it might

The pages which follow are intended as contributions to the wider understanding of the interest and excitement in contemporary science on the occasion of the 133rd annual meeting of the British Association at Swansea from September 1 to 8.

have been if all women of child-bearing age had produced their full biological quota of children. In other words, it looks as if it is quite possible for a growing population to limit its rate of growth even without the full apparatus of modern contraceptive techniques. The way in which the population of Britain took another spurt forward in the second half of the nineteenth century is a little more puzzling. Part of the explanation is that children died less frequently in infancy, and therefore survived to have children of their own, but it also seems that comparatively prosperous families were able deliberately to decide to have larger families.

This brief history is relevant to what is happening now elsewhere in the world. First of all, the rapid growth of the world's population in the past thirty years is almost directly attributable to the way in which better medicine and better insecticides (used against the mosquitoes which carry malaria, for example) have enabled hard-pressed communities to keep their children alive until middle age. In some quarters, quite misguided, this is held to be a proof that medicine and insecticide technology can be "blamed" for the growth of the world's population. The truth is, of course, quite different. In present circumstances, there is good reason to think that one of the conditions that must be satisfied before rapidly growing populations take the steps to limit the pace of growth which seem to have taken place in the eighteenth century in Britain is that there must be a still further improvement of medical care in infancy. In South America, India and South-East Asia, it seems to be quite commonplace that mothers when asked how many children they would like to have provide higher answers when the infant mortality is high. For reasons which are obvious and which cannot be dismissed, they take the view that they must have enough babies to make sure that one at least will grow up to be an adult male. But it is clear that prosperity is another condition to be met, as recent experience of a falling birth rate in places such as Hong Kong and Singapore bears out. As it happens, all this is quite familiar and, to say the least of it, it is surprising that the prophets of doom have made so little of this to them unpalatable evidence.

What this implies is that there is every reason to expect that social forces, already apparent in the recent demographic history of Britain, will in due course help to control the populations of developing countries. To be sure, it is important that steps should be taken to encourage these developments. If the true objective of those who preach calamity is to bring about a stable solution, they would be much better advised to advocate those kinds of social innovations that might encourage stability than to complain that famine is only just around the corner. In doing so, of course, they would be driven to recognize that one of the ironies of the contemporary problem of population growth is that the countries where the population is growing most quickly are so compelled to invest resources in schools and medical facilities that they have very little for the kind of industrial investment that might in the long run make them economically prosperous, itself a precondition for population stability. The moral in this is no doubt that foreign aid of the right kind could make an important contribution to the stabilization of the world's population. The modern equivalent of Malthus's position is that population growth brings impoverishment. It is irresponsible of the doomsday men to shirk these subtleties, and to settle for a kind of biblical choice between survival and calamity.

The alarm which attends the public discussion of the population problem crops up everywhere. Pollution, for example, is now so widely held to be a threat to the survival of orderly society that there is a danger of a serious distortion of social priorities. DDT and the other chlorinated hydrocarbons which have functioned as insecticides since the war are good examples. The materials are persistent, and are toxic to animals which concentrate them. It seems to be well established that birds such as peregrine falcons and eagles are particularly affected by these insecticides. At the same time, however, nobody would suppose that the damage done to eagles in, say, North America by insecticides is anything like as great as the damage caused by the illegal shooting of eagles by farmers in the Dakotas and elsewhere in the Middle West of the United States. And, moreover, there is no evidence at all that these insecticides have been damaging to people. To be sure, experiments in the United States, admittedly inadequate and only preliminary in character, have shown that the chlorinated hydrocarbons in very large doses can increase the incidence of tumours in mice, but there is as yet no sense of what bearing this may have on human health, although it does seem clear that the long range effects of DDT and similar materials are unlikely to be more damaging than a great many other familiar chemicals in the environment, and certainly less damaging than some of those which have in the past few decades been eliminated altogether—the use of carbon disulphide in vulcanizing plants, for example. Although the persistence of DDT argues for close control of the way in which it is used, it is surely entirely misguided that an over-zealous scorn for DDT and related chemicals should rob the world at large of the benefits they may have in the prevention of malaria, in the improvement of precisely the kinds of agricultural productivity that bear on the problem of how to feed the growing population and which are, in any case, a good deal less damaging to the environment than some of the materials—sodium arsenate, for example—which they replace. To be sure, it is always possible to hope that more subtle methods of controlling insect populations, ranging from the deliberate infection of insect populations with parasites to the use of pheromones for baiting insect traps, may in due course help to control populations of unwanted insect pests without causing serious side effects. But it is only proper that those who advocate the abolition of DDT on the grounds that it will bring calamity should warn the agriculturists whom they would deprive that biological control is still a technique applicable only in particular circumstances.

Population and pollution are, however, only two of the spectres which perplex commentators on the relationship of science and technology with society. Other people fear that carbon dioxide in the atmosphere will eventually produce such a powerful greenhouse effect that the Antarctic ice cap will be melted but, in reality, nobody can be sure that the effect will be that predicted and in any case the accumulation of carbon dioxide in the atmosphere is by no means the inexorable process that the doomsday men suggest. Other recent fears—the current alarm about the way in which exhausts from supersonic aircraft may destroy the ozone layer in the atmosphere and thus expose people to dangerous doses of ultraviolet light—are similarly unfounded, but this does not undermine their usefulness in the hands of those who seem anxious to demonstrate that the world is about to end.

In the long run, the most interesting feature of the present wave of gloomy speculation is likely to be the sudden emergence of what will, no doubt, be considered to have been a wave of fashion. Most probably, the real threat of global catastrophe posed by nuclear weapons in the forties and more especially the fifties is a part of the explanation why there should now be such concern that global calamity might arrive. But, paradoxically, the threat of nuclear war on a catastrophic scale is now in retreat. That the fifties should have left behind such a sense of bewilderment about the way to strike a balance between the useful applications of technology and the unwanted side effects which it can produce is a social phenomenon of great interest. Is it possible that the explanation is to be found in the sharp contrast between the doomsday view now prevalent in advanced societies and the optimism about science and technology still to be found where prosperity is, for the time being, less in evidence?

An extract from an address to Section X of the British Association.

Science, Statistics and Society

A. W. F. EDWARDS

Department of Medicine, University of Cambridge

Statistical techniques primarily developed for the natural sciences are finding increasing application in the social sciences. At a time when there is little agreement among statisticians about the properlogical basis of statistical inference, the use of equivocal methods for the interpretation of scientific data of social relevance, and the misunderstanding of some of the basic tenets of inductive inference, may have grave social consequences.

STATISTICAL theory has been developed, principally over the past hundred years, in response to the needs of astronomers and physicists and, more recently, to the needs of medical, biological, and agricultural research workers. The body of methods which has thus been created is now increasingly finding application in the social sciences, with the result that techniques originally invented for the reduction of astronomical observations, or for the testing of hypotheses in controlled experimental conditions, are being applied in areas which are socially sensitive. But are they the appropriate techniques? Are they sufficiently clearly understood to contribute positively to the analysis of data in the social sciences, or do they obscure the train of thought by substituting rhyme for reason?

As the "centre of gravity" of research moves from the physical, through the biological, to the social sciences, statistics (in its inductive, as opposed to purely descriptive, role) becomes of increasing importance as the filter through which the information contained in the data will pass. But in the minds of most non-statisticians this filter is a black box, filled with mysteries, even though provided with labelled inputs and outputs. The black box has recently adopted the dimensions of a computer centre, complete with packages of statistical programs available on demand to all who conform to their input requirements. Though admitted to be full of mysteries, it is widely supposed that the black box operates on principles generally accepted by statisticians. It comes as a shock to discover that the statistical world is in a ferment of disagreement over these principles. Not even does the concept of a null hypothesis and the associated simple test of significance, that hallmark of statistical numeracy demanded by the editors of progressive journals, pass unchallenged.

Controversy in Statistical Inference

As an example, consider the following question set in a university examination for a BA in Sociology[1]:

"Let μ be the true IQ of student X. It is known that his scores on test Y are normally distributed with mean μ and standard deviation 4.00. The test is administered to him on occasion Z and he scores 125.

(i) What is the maximum-likelihood estimator of μ?

(ii) Test the hypothesis that $\mu = 120$.

(iii) Comment upon the statistical bases of the methods used to solve (i) and (ii)."

A well informed candidate might answer as follows:

"(i) The maximum-likelihood estimator of μ is the sample mean; in this case the estimate is therefore 125.

(ii) See (iii).

(iii) The statistical basis of (i) is in dispute. Some hold that it is reasonable to contemplate a 'true' value, and that the maximum-likelihood estimator is to be preferred because it has optimum properties under repeated sampling, too complex to be discussed here. Others hold that the concept of a 'true' value is vacuous, and that the maximum-likelihood estimate is to be taken because it offers the best fit to the data, in the sense of maximizing the likelihood. It should be noted that still others reject the use of maximum-likelihood on either justification.

"There are at least six points of view on (ii):

(*a*) The question does not admit a statistical solution.

(*b*) A test may be constructed on Neyman–Pearson principles, according to which the hypothesis will be accepted or rejected, as in a decision procedure, the justification being in terms of repeated sampling.

(*c*) A test may be constructed on Fisher's principle in which the probability of the observed result, or one more extreme, on the basis of the null hypothesis, is used to judge whether that hypothesis is to be rejected. It might be 'one-tailed' or 'two-tailed'.

(*d*) The fiducial distribution of μ may be found, and a statement of fiducial probability made about the null hypothesis.

(*e*) A Bayesian position may be adopted, in which a prior probability distribution for μ, representing knowledge about μ prior to the observation, is compounded with the likelihood function derived from the observation, to form a posterior distribution for μ. There is no complete agreement over a suitable prior distribution, nor over the most suitable form of test once the posterior distribution has been found.

(*f*) A pure likelihood position may be adopted, in which the null hypothesis is compared with the most likely alternative hypothesis using the likelihood ratio.

"In view of the unresolved arguments over the applicability of these methods, I am unable to answer (ii) to my satisfaction, though it should be noted that since the distribution is specified as normal, some of the methods would give very similar answers, a circumstance that has helped to obscure important logical distinctions."

There is, of course, no time to teach such a critical approach. "In the behavioural sciences in general the overwhelming practice both by researchers and those responsible for statistical training has been to ignore the issues raised by the critics and to continue doing things as before."[2]

In an earlier article[3] I examined some of the logical problems of the conventional approaches, concluding in favour of the use of likelihood as the basis of the calculus for inductive inference[4]. In the present article I air some of the more elementary points in probability and statistics which are often misunderstood, hoping thereby to encourage those who already harbour suspicions about many conventional arguments not to allow themselves to be dazzled by statistical brilliance.

The Null Hypothesis

No argument should be accepted simply because it relies on some orthodox statistical practice. Statistical techniques need to be viewed as aids to, and not substitutes for, thought. They will not help if they are not clearly understood, and they may seriously hinder. Take, for example, the null hypothesis, widely acclaimed in the social sciences as the *sine qua non* of objective data analysis, but viewed with suspicion by others as providing "the basis for the simplest decisional procedures which have so effectively colonized the more gullible sciences"[5]. Not so many years ago responsible people arrived at sensible conclusions from bodies of data by an intuitive process that can only be described as "judgment", in which their training, their experience, and their unique way of thinking each played a part. Such a subjective approach is now viewed with scorn; instead it is argued that we should adopt the objective statistical approach of setting up a null hypothesis and testing it. But how are we to choose the null hypothesis?

A notorious example is provided by the current debate on the inheritance of intelligence, in which it appears at first sight that a suitable null or "empty" hypothesis is that intelligence in man contains no inherited component. But since data on the inheritance of intelligence are difficult to acquire, and the subject of much special pleading, a "rejection of the null hypothesis at the 1% level of significance" is hardly to be expected. Repeated non-rejection of the null hypothesis is too easily interpreted as indicating its acceptance, so that on the basis of no prior information coupled with little observational data, the null hypothesis is accepted.

Far from being an exercise in scientific objectivity, such a procedure is open to the gravest misgivings. What used to be called prejudice is now called a null hypothesis, and what used to be called judgment is now called prejudice. For may we not, with equal absurdity, adopt the null hypothesis that all variations in intelligence are genetic in origin? Thus we find that not only are the statistical methods appropriate for testing a null hypothesis in dispute, but the very concept of such a privileged hypothesis is a potential danger.

If we base our actions—such as social policies—on such an approach, we lay ourselves open to the tyranny of null hypotheses, and the prejudices of those who choose them. Thus it would be "natural" to advance the null hypothesis that family allowances have no effect on family size, but—in the absence of evidence on the point—it would be absurd to act as if this hypothesis were true just because it has been designated "null". A further example is provided by discussions of whether violence and obscenity on television corrupt: the absence of positive evidence is sometimes taken to justify the assumption that they do not.

In the more abstract world of pure scientific research, in which such statistical techniques evolved, questions of prejudice less frequently arise, and are generally less important when they do. But in other fields the adoption of methods which are so open to misuse is to place a dangerous weapon in uncritical hands: "The enthusiast whose sole interest in science is to find support for a preconceived social policy, not only deceives himself, and perhaps others who are not aware of his bias, but inevitably brings some discredit upon all other workers in the same field"[6].

Moral and Metrical Equality

One of the characteristics of our age is a preoccupation with equality. In its moral sense, "the condition of being equal in dignity, privileges, power, etc., with others"[7], surely no justification is needed, yet there is a tendency to seek one by predicating moral equality on "metrical" equality, "the condition of being equal in quantity, amount, value, intensity, etc."[7]. There is thus often a strong motive for assuming metrical equality solely on the basis of no evidence to the contrary, an assumption to which some statistical theories lend support.

In the approaches which depend on the null hypothesis, scientific respectability is apparently conferred on the concept of equality, for if we have no information on the variability of a statistical population, an apparently "empty" hypothesis is that all the members of that population are the same in respect of the attribute in question. On many socially important problems it is regarded in some quarters as irresponsible to challenge the null hypothesis with data, yet in truth the hypothesis itself is an exceptionally strong one in most applications, one which no thinking scientist would accept were it not for the influence of current statistical practice.

In the Bayesian approach a similar role is played by Laplace's *Principle of Indifference* applied to beliefs. Ignorance is represented by an equality of probability, a postulate which many cannot accept because they hold that a probability statement is invariably informative, and that the only permissible expression of ignorance is no statement at all[4].

The predication of moral on metrical equality, and the unwarranted assumption of the latter, are weak points in a common argument; the first is an example of the best causes attracting the worst arguments, whilst preoccupation with the second, and hence a concern with relative rather than absolute standards, heralds an inflation which is not only monetary.

The assumption of equality may indeed have precisely the opposite effect to that which it is intended to have by its well meaning proponents. Thus, returning to the question of intelligence, if we assume that each child has the same intellectual potential whatever his parentage, and if this turns out to be a false assumption, those at either extreme of the Mendelian lottery will not receive the special treatment necessary to increase social equality. As has been observed on more than one occasion recently, any attempt to allocate university places or degree classes in such a way that each group (be the grouping by class, race, creed, sex, or any other category) is represented in proportion to its numbers may have most undesirable effects. For should any such group in fact be less well endowed genetically than another, it will soon become common knowledge that a first-class degree (say) is of a lower standard when the holder is a member of that group. Membership of a particular group will then be seen to be relevant to the assessment of the individual, which is precisely the situation we wish to avoid. Perhaps these matters were more clearly understood before the advent of statistics. In the sixteenth century it was well known in Cambridge that the intellectual reputation of Trinity College was founded on the fact that its fellowships were not restricted by place of birth: in most other colleges there was a restriction on the number of fellows from each county, in an attempt to ensure national equality[8]. The system fell into disuse.

Causation, Correlation, Classification

The confusion of thought contained in the failure to distinguish the concepts of causation and correlation is so elementary that it would not need stressing were it not for its grave consequences. It is a distinction which statisticians are invariably at pains to make clear, and hence differs from those misconceptions which have their origin in statistical theory. The confusion of the two concepts is a major source of prejudice, especially in race relations.

At the same time as techniques, now regarded with suspicion by many statisticians, are sweeping through the social sciences, some of the more straightforward consequences of probability theory are neglected. Perhaps the most important of these is the fact that there are two ways by which we may acquire information about an individual Suppose I speak to you on the telephone and we arrange a meeting, never having met each other before. I know from your voice that you are a man, and from your name that you are an Englishman. Even though this is all the information I possess about you, it enables me to make a statement about your height, thus: the probability that you are between 5 feet 8 inches and 5 feet 8.5 inches tall is 0.8, if I take as my datum the fact that Englishmen are normally distributed in height with a mean of 5 feet 8 inches and a standard deviation of 2.5 inches.

Such a statement is poised half way between complete ignorance and complete knowledge of your height; that is why it is phrased in terms of probability: "It has been often recognized that any probability statement, being a rigorous statement involving uncertainty, has less factual content than an assertion of certain fact would have, and at the same time has more factual content than a statement of complete ignorance. The *knowledge* required for such a statement refers to a well-defined aggregate, or population of possibilities within which the limiting frequency ratio must be exactly known. The necessary *ignorance* is specified by our inability to discriminate any of the different subaggregates having different limiting frequency ratios, such as must always exist"[9].

The important point is that my statement refers to *you*. It is not true to assert—to take a recent example from the discussion on education—that "characteristics of social groups have no implications for the kinds of individual differences which are the concern of education"[10]. For such a statement to be valid, either the social groups must not differ in respect of the characteristic, or the logic of probability theory is at fault. The first point needs to be demonstrated. The process of induction outlined above is very old: indeed, the whole point of giving objects names at all is to classify them, and hence to convey information about them. If I say "I own a dog" you know certain things about the animal I keep in my house, though you have not seen it.

The second way in which we acquire information about an individual is by direct measurement. Thus, when I meet you, I may judge your height "to the nearest inch", or, if I carry a measure, "to the nearest tenth". But this new information does not annihilate the old; indeed for over two hundred years we have possessed a theorem which enables us to combine information from these two sources: Bayes Theorem.

The technical details of the theorem cannot now detain us, but reading sociological articles leaves a distinct impression that this most important theorem has not yet penetrated into the thinking of social scientists. In their concern to treat the individual as an individual they deny the relevance of group characteristics; but this is to deny Bayes Theorem, and hence to suppress some relevant information. Objectivity is not to be achieved by the suppression of information.

One of the consequences of the theorem is that, as individual measurements become more reliable, they become more important relative to the "prior" information derived from group characteristics, as is to be expected: a doctor who books a maternity bed for one of his patients on the basis of standard tables for the duration of pregnancy is making the best use of the meagre information at his disposal; but when the patient telephones to say that labour has started, the new information far outweighs the old.

The problem of the applicability of Bayes Theorem is a deep one. It is clearly appropriate in scientific situations such as those described above, where information must not be discarded. But it is excluded when considering criminal cases in courts of law, in which guilt is pronounced only if it is "beyond all reasonable doubt". If the direct evidence is so meagre that the prior information, such as provided by previous convictions for the same type of offence, is relatively important, then there will still be "reasonable doubt" about the guilt of the accused. Besides which, justice requires that every case be decided "on its merits", since the accused may be a reformed character for whom evidence of previous convictions would be irrelevant. He should have the benefit of the doubt.

It is in the assessment of the merits of the individual that the operation of Bayes Theorem needs the closest scrutiny. Thus in considering applicants for a post, we should ideally evaluate the suitability of each and every one with such diligence that any prior information is of negligible importance in our final decision. In practice, the effort is too great. We therefore invent qualifications, such as degrees and certificates, and only consider applicants who hold qualifications we consider appropriate: professors are almost invariably appointed from among graduates (George Boole was an exception). An inevitable cycle then starts. From being an indication of suitability for a post, a degree becomes a prerequisite. It thus becomes desirable in itself; demand exceeds supply; expansion occurs to meet the demand, and the supply is soon more than adequate. The surplus graduates are aggrieved that they cannot find employment of the kind that graduates formerly enjoyed. An inflation has taken place because the original purpose has been partially forgotten, and the cry is raised for the abolition of the system.

The consequences of misunderstanding some of the basic tenets of inductive inference, and of uncritically accepting and applying statistical recipes whose foundations are still in dispute, are grave. Quantitative work in the social sciences suffers and inappropriate modes of thought are introduced into otherwise rational discussion.

We need not applaud the extreme reaction of Hogben[11] to the penetrating advances that have been made this century towards a better understanding of statistical inference, but we would be foolish not to heed his warning: "Laboratory experiments will have to stand on their own feet without protection from a façade of irrelevant computations. Sociologists will have to use their brains. In my view, science will not suffer".

Fossilmanship in East Africa

SARAH BUNNEY

Recent discoveries in the Plio-Pleistocene deposits of East Africa may call for a re-examination of man's evolutionary history.

HAD a cantankerous camel ridden by Richard Leakey not stalled one August day in 1969 in the desert heat of northern Kenya, palaeoanthropologists might have missed one of the most interesting discoveries of recent years—a skull, intact but for its teeth and jaws, of an early hominid more than two and a half million years old. But for the bad humour of the camel, as Leakey recounted later in the *National Geographic Magazine*[1], he and his party would not have broken camp earlier than was planned and would probably not have come upon the skull lying in a dry stream bed in the Ileret area on the east side of Lake Rudolf. The fossil resembles[2] *Australopitheicus boisei*, the robust form of australopithecine known from East Africa and, by coincidence, Leakey found it almost ten years to the day after his mother, Dr Mary Leakey, discovered the first representative of this species in Olduvai Gorge, farther to the south.

Hunting for fossil man thus has its lucky moments—and the Leakeys certainly seem to have their share of them—but as the pages of *Nature* for the past three or four years show, this activity requires not only a remarkable flare for knowing exactly where to look for fossils but also a willingness to work sometimes under the most inhospitable conditions in what is often unexplored territory; recent palaeontological expeditions to East Africa have made history in more ways than one.

The rewards have, nonetheless, been rich. Richard Leakey's chance discovery in 1969 of the robust australopithecine skull in the Rudolf area and the associated hominids and fossil vertebrates collected in that year and in the previous year's season were but foretastes of what was to follow in 1970. The results of this last season's work, described earlier this year[3], added not only another fifteen or so hominids to the Rudolf list (including what may prove to be specimens of an early representative of *Homo*), but also extended the vertebrate collection to some six hundred specimens[4].

Richard Leakey is wisely, though tantalizingly, reticent about the taxonomic affinities and dates of these hominids until more detailed anatomical and geological analyses have been made, but there now seems little doubt that this part of East Africa will be as significant in the study of human origins as Olduvai Gorge in Tanzania made famous by Richard's father Dr Louis Leakey.

Being Plio-Pleistocene in age, the Rudolf deposits (see Fig. 1), and those in the Omo Valley in Ethiopia[5,6], extend back in time from those at Olduvai by another two million years and, together with the other finds of australopithecines elsewhere in Kenya, they help to fill in the gap between the *Ramapithecus* stage of human evolution, of Miocene times (see the recent reviews of this subject[7-9]), and the early Pleistocene *Australopithecus* remains from Olduvai and the South African sites. It might therefore be thought that the jigsaw of human evolution was neatly being pieced together. But is as becoming clear from the preliminary results of the Rudolf expeditions[3], not all the pieces are fitting into the puzzle in quite the way that palaeoanthropologists have been led to expect and it seems likely that Richard Leakey's interpretations of the Rudolf material will be as contentious as those his father made regarding the *Homo habilis* specimens from Olduvai.

Coexistence

The chief point of interest in the reports to date[2,3] of the Rudolf investigations are Richard Leakey's suggestions that more than a million years ago the genus *Homo* coexisted

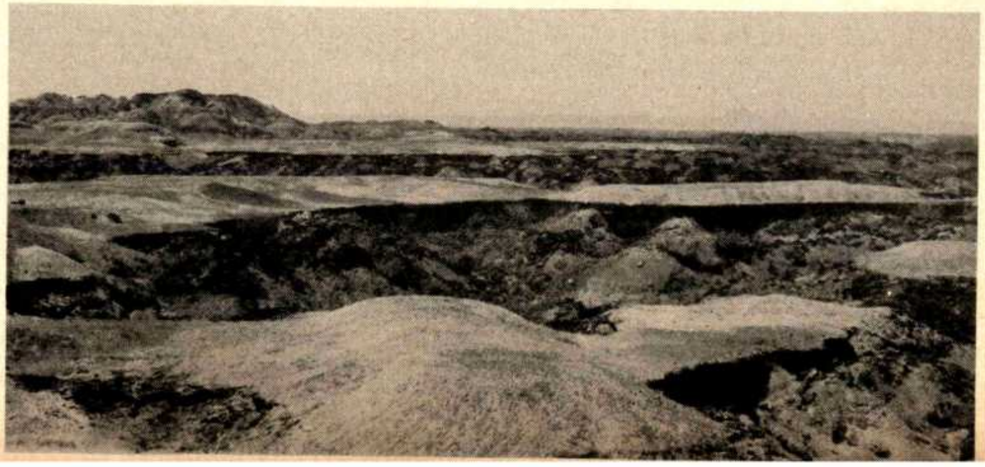

Fig. 1 Pleistocene exposures in the Koobi Fora area, East Rudolf.

with *Australopithecus* in this part of East Africa at the beginning of the Pleistocene, and therefore that the two genera may well have been quite separate and distinct at this time. He also revives the idea that the differences in size and morphology between the gracile and robust types of australopithecine (both of which have been found in stratigraphically similar deposits in the Lake Rudolf area) relate to sexual dimorphism and the two are thus not separate species or subspecies as is usually held to be the case.

Richard Leakey bases his claim for *Homo* at Lake Rudolf on three specimens—two mandibles (both are fragmentary but KNM–ER–730 is more complete than KNM–ER–731) and an incomplete femoral shaft (KNM–ER–737). Further discoveries and more detailed examinations are obviously required before this claim will be seriously considered by other workers—what is now needed, in particular, is some agreed definition of a complex of morphological features characteristic of the line of evolution leading to man—but if these specimens are accepted as *Homo*, and KNM–ER–730 seems a particularly good candidate for inclusion in the genus, they may be the best evidence so far of the genus outside Java where *Homo erectus* is known. Richard Leakey has so far published no dates for his *Homo* sites. It seems very likely that they are more than a million years old, but it is not clear from the reports whether they are as old as the age of 2.61±0.26 million years which is the date given by Leakey[2] for some of the Rudolf hominids including the specimen (KNM–ER–406), *Australopithecus* aff. *boisei*, mentioned earlier.

This is not the first suggestion that *Homo* and *Australopithecus* were contemporaneous in some parts of Africa. For several years, Louis Leakey has claimed that a more advanced form of hominid, the famous *Homo habilis*, coexisted with *Australopithecus* in the Olduvai Gorge locality for about a million years and that this form and not *Australopithecus* was responsible for fabricating the primitive tools recovered from Beds I and II, known as the Oldowan culture. Only recently[10], he has published an account of another *Homo habilis* specimen (OH 24) which was discovered in 1968 in Bed I at Olduvai. The fossil, nicknamed "Twiggy", was found in a very crushed state and its inclusion in *Homo* is likely to be questioned by the several workers who regard *Homo habilis* as an East African variant of the gracile *Australopithecus africanus*, a species which was known first from the South African sites.

There have been similar doubts regarding the material from Swartkrans in South Africa, once known as "*Telanthropus capensis*" and subsequently reclassified by Professor T. Robinson as *Homo erectus*. According to Robinson and some other workers, this material is evidence of the coexistence in the early Middle Pleistocene of a more advanced hominid than the robust australipithecine. *A. robustus* (formerly *Paranthropus*) known in large number from that site. But this claim has been questioned by some authors who hold that the so called *Homo erectus* material, like *Homo habilis*, is simply another variant of the polytypic *A. africanus* population of the time. This issue was reopened last year with the description by Dr. C. K. Brain and his colleagues[11] of a reconstructed skull from Swartkrans which they claim is a representative of the genus *Homo* but to which they assign no specific name. The niceties of this taxonomic problem, like those of *Homo habilis*, will no doubt continue to be argued about by Wolpoff[12] and others for several more years to come.

Part of the reason for the current confusion over early hominid taxonomy lies in the fact that although there is now plenty of cranial material, particularly teeth and lower jaws, postcranial remains of *Australopithecus* are rare. It is only through detailed analyses of such bones that some idea can be obtained of the gait and stance of the creatures. One of the criteria used for distinguishing *Homo* from the pre-human stage is his upright bipedalism, and the limb bones of early hominids which can provide clues to the origin of bipedal locomotion are therefore particularly valuable. The hominid limb material from Lake Rudolf, claimed by Richard Leakey[3] to be representative of both the *Australopithecus* and *Homo* forms, should thus be very useful.

Until the Rudolf discoveries, a complete femoral shaft of an australopithecine was unknown, although femoral ends of robust forms had been recovered several years earlier from Swartkrans (SK 82 and 97) and from Olduvai (OH 20) (see ref. 13 for a discussion of these), and a reconstruction of a femur of a gracile form has been made from material recovered at Sterkfontein. The Rudolf material should therefore allow useful comparisons with this australopithecine material, with the femur of the supposed *Homo* from Rudolf, and also with postcranial material of undisputed *Homo erectus* such as that recovered in 1970 from the Middle Pleistocene Bed IV at Olduvai and described recently in *Nature* by Dr M. H. Day[14]. This last material (OH 28) was found in association with an Acheulean industry and is the first direct association of tools with *Homo erectus*. This association naturally does not necessarily imply that *H. erectus* was responsible for the industry, but Mary Leakey[15] thinks it likely because there is other evidence at Olduvai of a possible link between early Acheulean hand axes from Bed II and *Homo erectus*. Day has also been able to compare[14] OH 28 with femora of approximately the same age from Choukoutien in China and with the femora claimed to be of the same age from Trinil in Java.

Antiquity

In spite of the considerable confusion over the fine distinctions between *Australopithecus* and *Homo*, the new work in East Africa is confirming the view that there were marked morphological variations between populations of early hominids and that these variants can be broadly grouped into gracile and robust forms which persisted relatively unchanged for several million years. For just how long they persisted is being brought out by some of the recent discoveries in Kenya and elsewhere. Until a few years ago, australopithecines were thought to have evolved as a distinct group only about a million years ago; even with the redating in the early 1960s of the timing of the beginning of the Pleistocene epoch the antiquity of these hominids was thought to be only as much as about 2 to 3 million years. With the discoveries of new Plio-Pleistocene deposits in Kenya and Ethiopia, however, and more reliable radiometric dating techniques it is becoming clear that *Australopithecus* had evolved by the end of the Pliocene.

The oldest undisputed australopithecine material known to date seems to be the portion of a lower jaw with one molar intact found by Professor B. Patterson's team at Lothagam Hill near the south end of Lake Rudolf in Kenya. This fossil is thought to be a representative of the gracile form of australopithecine and its date of 5.5 million years puts it well and truly in the Pliocene. Patterson and his colleagues also have the distinction of finding part of a hominid humerus, which likewise probably belonged to a gracile form in deposits at Kanapoi in Kenya. The date of this specimen was put at 2.5±0.2 million years when it was described in 1967 by Patterson and Professor F. C. Howell, but more accurate dating of the lava flow overlying the deposits in which the fragment was found and comparisons of the mammalian fauna with those from the Omo Valley and elsewhere suggests that the Kanapoi hominid is between 4.0 and 4.5 million years old. In their turn the Omo Valley hominids seems to have a range of between 2.0 and 4.0 million years[5,6]. At Rudolf the dating has not been completed, but the age already given to the robust skull KNM–ER–406 antedates the earliest hominid

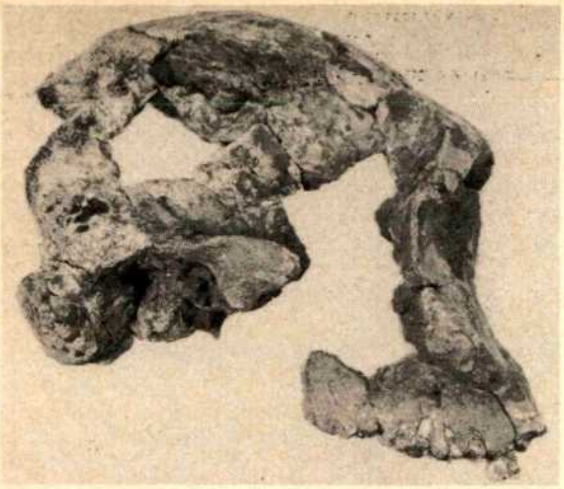

Fig. 2 An almost complete right half of a cranium of an australopithecine collected in 1970 from the Ileret area, East Rudolf.

from Olduvai by about 0.8 million years and similar robust types from Swartkrans and Kromdraai *A. robustus* (≡*Paranthropus*), by about 1.5 million years.

Whether australopithecines older than 5.5 million years will be found is another matter, though Bishop *et al.*[16] claim to have recovered the upper molar tooth of a hominid from the 9 to 12 million-year old Ngorora Formation in the Baringo District in Kenya. Louis Leakey has described this specimen as having some affinities to *Kenyapitheus* (equivalent to *Ramapithecus* of Simons and Pilbeam) and some to both *Homo* and *Australopithecus*. Judgment on this find will no doubt be reserved until further discoveries are made from this locality. It is nonetheless clear that the fossiliferous seciments at Baringo are going to be particularly useful in unravelling the evolution of vertebrates during the Pliocene.

It was during the Pliocene that many African mammalian groups had their origin and diversification; other groups, by contrast, became extinct. Comparisons of faunas from different localities can thus provide useful information about the evolution of mammals in Africa and the dating of one faunal assemblage can form a standard of comparison for other faunas. This obviously has a bearing on the correlation of important hominid-bearing sediments. Maglio has already produced a tentative correlation[17] for some Plio-Pleistocene deposits in East Africa based on the remains of fossil elephants found in them. Isolated teeth of Proboscidea are common in these sediments and are often well preserved because of their large size and thick enamel covering and are therefore useful stratigraphical indicators. Maglio has also compard the rich collection of vertebrates from Lake Rudolf[4] with the assemblages known so far from the Omo Shungura Formation and from the lowermost beds at Olduvai. Two of the species of elephant recovered at East Rudolf include the earliest known occurrences of the *Elephas* and *Loxodont* lineages and indicate that the Koobi Fora I beds at this locality are slightly older than the Kanapoi and Lothagam Hill deposits. There is also an indication[18] at East Rudolf of an older Mio-Pliocene sedimentary and volcanic complex in the Suregei Plateau, and this may provide crucial faunal remains for comparisons with those from Baringo. There is a chance too that some very early hominids will turn up here.

Robust and Gracile

As has been stated, the oldest unequivocal hominid is that dated at 5.5 million years from Lothagam Hill. This is a gracile form; the first sign of the coexistence of this type with the robust form comes later in time at Omo where Howell and his colleagues[5] have found fragments of two australopithecine variants which resemble *A. africanus* and *A. boisei* and which are between 3 and 4 million years old. The contemporaneity of robust and gracile forms has subsequently been confirmed by the results of Leakey's three seasons in the Lake Rudolf area. (The question of *Homo* in these deposits was discussed earlier; whether it is *Homo* or a variant of the gracile form does not alter the concept of two coexisting populations of early hominids.)

There has, of course, been much discussion about the relationships of the types of robust australopithecine—the northern *A. boisei* and the southern *A. robustus*. It is held by some workers, for example Tobias[19], that the East African robust form was ancestral to *A. robustus* and that the two were members of an over specialized line of early hominids which became extinct in the Middle Pliestocene. The genus *Homo*, according to this theory, evolved from the less specialized gracile *Australopithecus*. It has also been suggested that the size and morphological differences between the gracile and robust types relate to sexual dimorphism, but this view has not been widely accepted because it does not explain why at some sites there is a predominance of one type only and it is considered unlikely that just one sex, if the australopithecines were indeed widely sexually dimorphic, would be preserved at these sites. The recovery by Richard Leakey and his team of both types from the same stratigraphic levels should reopen this thorny problem. As already mentioned, Leakey believes that the two types represent the two sexes of the same austalopithecine species and that this population need not necessarily have been in competition for resources with his supposed *Homo* population; *Homo* and not *Australopithecus* would have been responsible for the Oldowan culture (see Fig. 2) recovered in 1969 from the Koobi Fora area (with a date of 2.6 ± 0.26

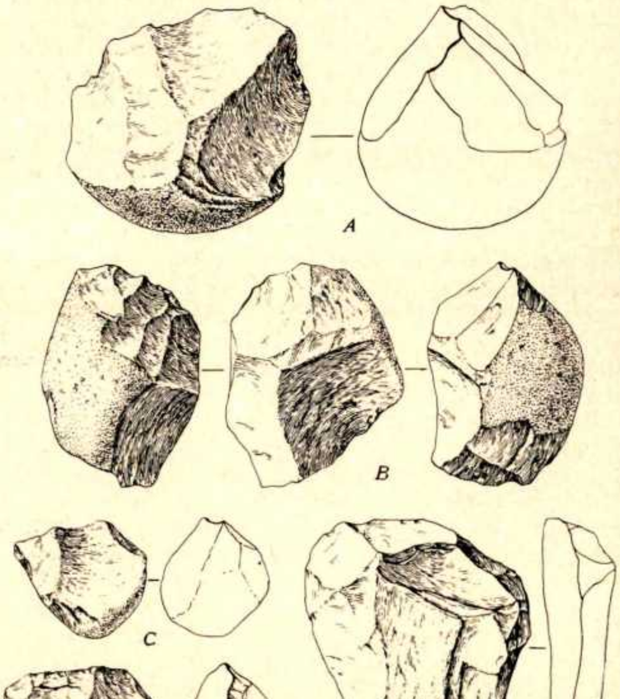

Fig. 3 Oldowan culture collected in 1969 from the Koobi Fora area, East Rudolf.

million years, it is the oldest collection of unequivocal artefacts known).

If *Homo* and *Australopithecus* did share a habitat at Rudolf in the early Pleistocene and the gracile form was indeed the female of the robust form, long established ideas in the palaeoanthropological world really would be upset. It would certainly require the re-examination of the theory that the gracile australopithecine was ancestral to *Homo*, and raises the interesting possibility that all the early Pleistocene australopithecines and not just the robust forms were members of a side branch of human evolution and doomed to extinction in the Middle Pleistocene.

The suggestion that *Homo* and *Australopithecus* were evolving in parallel in East Africa between three and one million years ago is not likely to be generally accepted at present, but it is one that deserves serious discussion. In this connexion, the recently described robust australopithecine cranium dated at between 1.1 and 1.2 million years from Chesowanja in the Baringo District is interesting. This specimen is described by Carney *et al.*[20] as less specialized than either the *A. robustus* or *A. boisei* types, and they claim that it possesses certain features characteristic of *Homo*. The cranium, unfortunately, is badly preserved and its significance in the evolution of man is questionable.

It is to be hoped that more important finds will turn up in the next few years. Who knows what might be recovered in the Lake Rudolf and Baringo area. Has the early hominid ancestor of *Homo* yet to be found?

Problems of Artificial Fertilization

R. G. EDWARDS

UNTIL recently, opportunities for scientific and clinical studies on human conception have been extremely limited, largely because of the inaccessibility of the ovary and the difficulty in obtaining preovulatory oocytes. One egg per month was a discouraging target and experience had shown that even this single egg was difficult to recover because ovulation could not be predicted with any degree of accuracy. In the past two or three years, considerable progress has been made with the clinical and scientific problems associated with the study of human fertilization and cleavage. The opening came with the discovery that human oocytes would undergo their final stages of maturation—those occurring just before ovulation—when removed from their follicles and placed in a suitable culture medium. These stages could be timed with considerable accuracy, and the availability of this human material provided opportunities for studies on meiosis, ovulation and fertilization[1]. Oocytes matured *in vitro* thus provided the material for studies on human fertilization *in vitro*, which was achieved two years ago.

Patients Involved

When fertilization had been accomplished using these oocytes, the emphasis of the work changed to include studies on patients in order to realize the potential of these studies for human infertility. There were various reasons for this extension into clinical studies. While oocytes matured *in vitro* provide good material for fertilization, they are unsuitable for studies on cleavage because observations in animals has shown that the resulting embryos fail to develop normally[2]. For normal development to full term, oocytes must be collected after completing, or almost completing, their maturation in the ovary (see Fig. 1). Endocrine methods were thus needed to induce follicular growth and oocyte maturation in the patients, the preovulatory growth of oocytes had to be timed exactly from the estimates made from cultures and surgical methods had to be developed for the collection of the oocytes just before ovulation. The achievement of these objectives has opened the possibility of growing and analysing cleaving embryos in culture, replacing them in the mother, and studying the processes of implantation. Each of these projects opens fundamental opportunities for the study of human conception. What progress has been made in these various areas of investigation?

The surgical methods for collecting human oocytes are perhaps almost as refined by now as they ever will be. Laparoscopy has proved to be a simple and very safe procedure permitting the necessary manipulations to be carried out on the ovary[3]. Oocytes are collected from more than one-half of the available Graafian follicles, and although the proportion could be improved the loss of one-half of the oocytes in this way is not holding up further developments in any serious manner. The timing of oocyte maturation and ovulation are also under fine control. None of the many patients so far examined has ovulated before the expected time, and many of the oocytes were fertilized soon after

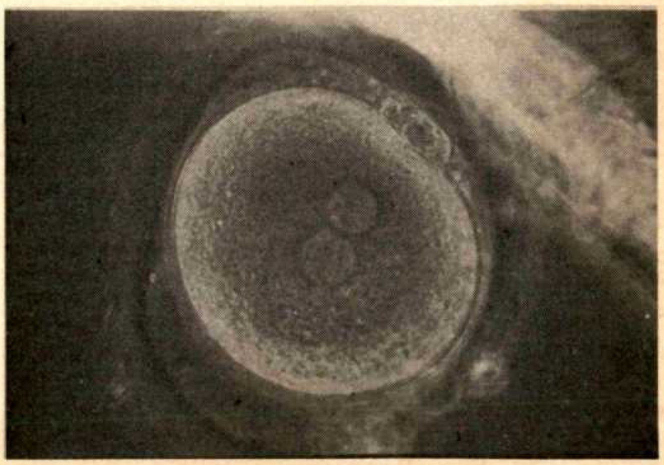

Fig. 1 Human pronucleate stage.

collection, showing that they were certainly preovulatory. The major problems in the initiation of follicular growth and oocyte maturation concern the response of the patients to the endocrine treatments, which are based on the use of human menopausal gonadotrophins on amenorrhoeic women[4]. Some of the patients have few or no preovulatory follicles after the treatment.

There are well known difficulties with the method—for example, the great variation between patients or even between successive treatments of the same patient[5]. Three or four preovulatory follicles are the minimum required to provide sufficient oocytes to work with. Measurements of the excretion of oestrogen in the urine of the patients during treatment provides some indication of their response to the treatment, particularly as a safeguard against overstimulation, but its usefulness as a measure of the growth of preovulatory follicles remains to be decided. There is some scope for improvements in the hormone treatment. The amount of gonadotrophin being administered to the patients is modest in comparison with that use for the treatment of amenorrhoea, partly because the patients have a normal menstrual cycle which might heighten their response. Simply raising the dosage of gonadotrophins should induce a greater response in most patients. Alternatively, the use of compounds such as clomiphene, to induce the release of endogenous hormones, might prove superior, cheaper, and more acceptable than the injection of gonadotrophins. Clomiphene is widely used in the treatment of female hypopituitarism, and should work well with cyclic patients. The recent purification of the gonadotrophin releasing hormones of the hypothalamus could well offer another alternative, provided that the dosage and response can be controlled.

Human Ova

Studies on the fertilization of mammalian ova *in vitro* have moved quickly in the past two or three years after a decade of uncertainty. Belief in the necessity of uterine spermatozoa had become almost dogmatic as a result of experiments involving mostly rabbit ova. Even the demonstration that hamster ova could be fertilized *in vitro* by epididymal spermatozoa[6] had scarcely shaken this fixed belief. When the conditions needed in the culture medium for hamster fertilization were defined, the work was extended to human material, using oocytes matured *in vitro* and washed, ejaculated spermatozoa. Fertilization was established using the same criteria defined for studies with animal ova[7]. Moreover, similar studies are now being extended to other species such as the mouse and cow, and even in rabbits spermatozoa have now been found to penetrate through the membranes of the ova. The culture media are simple: a basic Tyrode's solution is supplemented with bovine serum albumin, pyruvate, and bicarbonate to a *p*H of 7.6. Pyruvate is obviously an energy source, and the albumin presumably serves as a source of nitrogen or to stabilize cell membranes. The significance of the high *p*H, or of the contributions of the cumulus cells surrounding the ova, remain unexplained.

Media suitable for fertilization and for cleavage are rarely identical. The development of media to support the cleavage of human ova has not relied on experiments with mammalian ova to nearly the same degree. Simple defined media had been developed for the cleavage of mouse ova, following the recognition of the importance of pyruvate as an energy source during these early embryonic stages[8]. The initial attempts to culture human embryos utilized these media, but cleavage progressed only to the 8-celled stage[9] (Fig. 2). More complex media developed for routine tissue culture have proved much more successful. A medium composed of Ham's F 10 supplemented with calf or human serum, at a *p*H of 7.3 under a gas phase of 5% O_2, 5% CO_2 and 90% N_2, has supported development to the blastocyst stage[10]. Several blastocysts, each having 100 or more nuclei and several mitoses, have been grown under these conditions (Fig. 3). The inner cell mass, trophoblast and blastocoelic cavity were well defined, and some blastocysts expanded in culture. The blastocoel appeared to form from the secretions of large cells that accumulated at one pole of the morula. Modified body fluids are also reported to support the cleavage of human embryos[11]. According to one report, oocytes matured *in vitro* had to be fertilized by human spermatozoa previously incubated in the uterus of a monkey[12]; the abortive cleavage of the embryos might have been a consequence of maturation *in vitro* or some other cause.

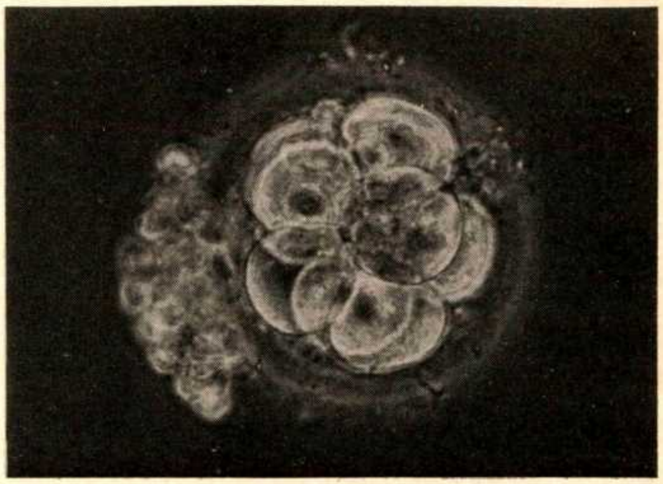

Fig. 2 Human eight-celled embryo.

Where Next?

Further development beyond the blastocyst stage must surely be the next study. This raises the question of whether the embryos will be able to implant in the mother, that is, if the uterus has been sufficiently stimulated by the endocrine treatments used to induce follicular maturation. Another question concerns the capacity of the embryos to implant. The indications are good: the pronounced differentiation of many embryos in culture augurs well for their continued development. Conditions in the mother also seem to be satisfactory: most patients have had a secretory endometrium, excreted suitable amounts of pregnanediol, and their induced cycle has resembled a natural cycle[3].

What is known of the capacity of the embryos for normal development? The criteria for cleavage are now well recognized, and provide the first safeguard. Several of the embryos have possessed a chromosome complement that appeared to be diploid, thus excluding the possibility of triploidy. Trisomy has not been excluded. Yet the more that

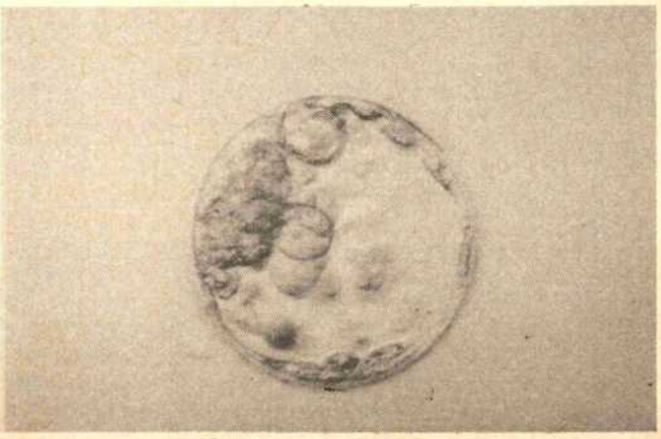

Fig. 3 Human blastocyst.

is learnt about natural human pregnancy, the more obvious becomes the conclusion that many embryos conceived naturally are trisomics, triploids or mosaics destined to perish in the first trimester. The possibility of trisomy in cultured embryos thus becomes less important, and especially since Down's syndrome can be identified in foetuses by amniocentesis. Nor should the problem of teratogenic development present undue difficulties, because widespread experience in animals and man has shown that agents known to be teratogenic in later stages of pregnancy are lethal to preimplantation embryos.

The immediate social consequences of the successful reimplantation of human embryos would be the cure of some forms of infertility, notably where the wife has occluded oviducts or the husband is oligospermic. There should be no criticism in giving these couples their own children: comments about overpopulation seem to be highly unjust to such an underprivileged minority.

The next development could well be the sexing of embryos before transfer. Rabbit blastocysts were sexed from the presence or absence of sex chromatin in small pieces of trophoblast excised by microsurgery[13]; the embryos recovered after a few hours in culture and some of them developed to full term in recipient females. The sex of all foetuses had been predicted correctly; this was the first occasion that the secondary sex ratio had been controlled in any mammal. Most efforts in this direction had been devoted to the attempted separation of X and Y spermatozoa, so far without any convincing success.

Improvements are now needed in the methods for sexing blastocysts. Two approaches are currently feasible: the identification of enzyme activity or of antigens determined by sex-linked genes. The activity of glucose-6-phosphate dehydrogenase (G6PD) and hypoxanthine–guanine phosphoribosyl transferase (HGPRT) have been studied in mouse embryos; it is not yet certain that these genes are sex-linked in mice as they are in man. Assuming that they are sex-linked, female embryos might be expected to possess twice the activity of male embryos. Unfortunately, levels of G6PD were dominated by the massive amounts of maternal enzyme "inherited" from the oocyte, and which declined steadily during cleavage[8,14]. The activity of HGPRT in embryos increased after fertilization, indicating that this enzyme was being synthesized during these early stages and, perhaps more important, that the sex chromosomes are active at this time[15]. This enzyme might thus be present in different amounts in male and female embryos. Evidence for sex-linked antigens is restricted to one report showing that the sex ratio of mouse offspring can be altered by interfering with the normal immunological processes of pregnancy[16]. Sexing blastocysts would be an excellent approach to the control of sex-linked mutant genes in man by avoiding the birth of affected boys. Strict control would have to be exerted over sexing if it could be demonstrated that widespread parental choice would seriously disturb the sex ratio in human populations.

Studies on human conception open new approaches to human problems including preventive medicine and family planning. More knowledge about the growth of ovulatory follicles, the secretions of the blastocyst or the components of capacitation could lead to the development of novel methods of contraception. Rational discussion is needed about the emerging social issues involved in these studies. Much of the debate so far has been unreal in the sense of being far removed from the actual clinical problems involved: constant reference to nuclear cloning is an example. Earlier remonstrations about the disposal of tiny blastocysts appear almost irrelevant when foetuses of four months' gestation or older are being aborted for social reasons. Alleviating infertility has even been criticized because more consideration is needed about the survival of the family unit in our society! Realization of the benefits that could accrue to many people should lead to more rational discussion and conclusions.

Assembly of Tobacco Mosaic Virus Particle

SCIENCE COLLE
Upper Circular
CALCUTTA

P. J. G. BUTLER
MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH

TOBACCO mosaic virus (TMV) is one of the best characterized viruses and consists of a long rod, which is composed of a helical array of identical protein subunits with the single stranded RNA lying in the helical groove between adjacent turns of the protein helix (for review see ref. 1). TMV was the first virus to be reconstituted from its RNA and protein[1] and has frequently been used as an example of the self-assembly process, and the protein alone is capable of forming rods which are structurally indistinguishable from the virus helix (see ref. 2). However, the protein also has many other polymorphic forms and this property complicates the understanding of the protein aggregation and has led to different theories being suggested to account for this process[2,3].

Recently, in a concerted attack on this problem in the MRC Laboratory in Cambridge, the structures of these different aggregates have been determined, using the electron microscope and X-ray diffraction techniques, and the conditions in which they occur defined[4]. The results support the ideas put forward some years ago by Caspar[2] that all the aggregates are the result of the same specific interactions as are found in the virus but slightly modified in the different polymorphic forms. The results also allow the mechanism controlling which protein aggregate will occur to be determined[5]. One of these aggregates, the disk, is found only in the conditions in which virus assembly occurs and it has been shown that growth of the virus does not occur by the addition of single protein molecules but rather by the incorporation of a whole disk at once[6]. The polymorphism of TMV protein is thus the basis for the rapid and specific formation of the virus from its protein and RNA.

Protein Aggregates

The aggregation of TMV protein can occur in one of two modes. The first to be structurally understood was the helix, in which the arrangement and conformation of the protein subunits is identical to that in the virus. The aggregation of the protein in this mode can be described as "quasi-crystallization" and the resulting rods are of indeterminate length, usually very large. The second mode can be described as "two-layer" aggregation and aggregates of this type are stabilized by an additional "pairing" interaction, which is not present in the helix, between the subunits vertically above each other. The movements of about 5 Å of the outer ends of the subunits, involved in this pairing, have been seen by 3-D image reconstruction from electron micrographs[7]. Because of the detailed geometry of the TMV protein subunit and of the intersubunit interactions, the layers curve round and the ends meet to form a closed torus consisting of two rings, each of 17 subunits (Fig. 1). It is this structure which is called the "disk".

The growth of the two-layer aggregates, from the trimer to the 32-mer, can be described as linear condensation polymerization, with each subunit adding with the same binding energy. The formation of the trimer, which begins the association process, and the addition of the final two subunits to close the disk cannot be described so simply. However, the energies of these various interactions have been calculated[5] and the resulting quantitative model does predict the observed sedimentation patterns.

A further complication with the two-layer aggregates is that under favourable conditions for the bonding interactions (at high ionic strength) the disks can stack on each other, to give even larger aggregates. This can result in a series of discrete, large aggregates in equilibrium with a range of small aggregates and gives rise to the sedimentation patterns which have caused much argument in the past. Still further complication is caused by the readiness with which the aggregation of TMV protein can become irreversible, presumably by some slight damage to the protein, and hence give aggregates which are no longer in equilibrium with the rest of the mixture. One such structure, the stacked disk rod, consisting of long rods of disks stacked on each other in a polar fashion, has recently proved important in the elucidation of both the structure[4,7] and control of formation[5] of the two-layer aggregates, just because of its size and the irreversibility of the disk aggregation within it, but even this had earlier caused considerable difficulties in the interpretation of experiments in which it had occurred.

The bonding in these two modes is very similar, with the pairing perturbation in the two-layer aggregates as the only major difference[4]. The importance of this pairing in limiting the growth of the aggregates to a single direction and thus causing the formation of a discrete aggregate, the disk, rather than the indeterminate sized helix, lies in the assembly process for the viral rods, which I shall discuss later.

When the conditions in which any particular aggregate contributes significantly to the equilibrium are determined (Fig. 1 of ref. 4), the *p*H is found to be the controlling variable for the mode of aggregation. As hydrophobic bonding is the driving force for aggregation[3], increasing both the temperature and the ionic strength will favour aggregation and cause large aggregates to form, but neither has a major effect on the mode of aggregation. The exact *p*H at which the transition between the modes occurs depends slightly on the temperature and ionic strength, but it is always about *p*H 6 to 7, with the helical aggregation predominating below the transition and the two-layer aggregates above. This transition *p*H is found to correspond to the *p*Ks of two carboxyl groups, which titrate abnormally in the virus[2] but not in the stacked disk rods[5], and in the titration of the protein helix an abnormally sharp release or uptake of protons correlates with the disaggregation or formation of the helix[8,9].

Control of Aggregation

The control effect can be seen qualitatively when the *p*H of a solution of the protein helix is raised and the turbidity, due to the long rods, disappears immediately as the rods dissociate to give the small protein aggregates (called the "A-protein"). If the *p*H is lowered again soon afterwards, the turbidity returns as the protein subunits reform helix. An important variation occurs if the protein is kept above the transition *p*H, in conditions where it forms disks, for long enough for the disks to be formed before the *p*H is lowered. In this case short, imperfect, helical rods are formed within 5 seconds, and these then anneal over a period of about a day to give long, perfect helices again. Close examination of the imperfect helices shows that they are composed of two turn segments of helix stacked on top of each other, with their ends not in register[4], each segment appearing to be formed from a single disk by it having dislocated under the influence of the high proton concentration.

Since the subunits in any single disk must change their mode of aggregation together, any such transition is inherently cooperative and can be considered to be allosteric, with the protons as the allosteric effectors. In this case the effectors act by protonating two carboxyl groups, to give two carboxyl–carboxylate pairs. This abolishes the repulsion between the charged carboxyl groups and concomitantly the pairing distortion of the two-layer aggregate, enabling the subunits to take up the strictly equivalent positions of the helix. Were it not for the carboxyl–carboxylate pairs the bonding in the helix would presumably be more favourable than that in the disk, but the unfavourable interaction of these groups acts as a negative switch to prevent helix being the most favoured aggregate under all conditions.

This negative, and energetically unfavourable, switching is in contrast to the position that is found in the cases where ionic interactions have been investigated in detail in other proteins. In haemoglobin, which in many ways forms a close parallel with the situation in TMV protein, salt bridges are formed between the chains in the deoxy form but not

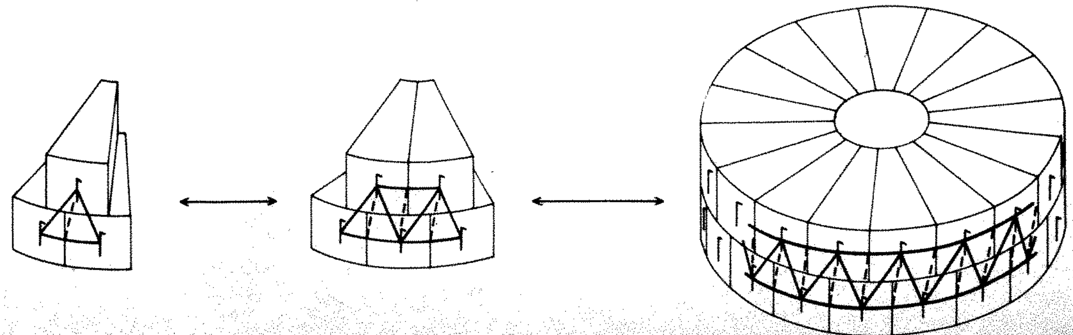

Fig. 1 Model for two-layer aggregation to form disks[5]. Subunits associate laterally in a linear fashion with polymerization in the axial direction limited by the pairing deformation[4] (shown by the dotted line). Other intersubunit contacts are shown by solid lines.

in the oxy form[10]. These bridges have to be broken to allow the quaternary structure change, which also involves a movement between the chains of about 5 Å, brought about by the ligand, to go from the deoxy to the oxy structure[10,11]. In both haemoglobin and TMV protein the allosteric transition is also influenced by other ligands, diphosphoglycerate in the case of haemoglobin and with TMV protein the viral RNA.

Protein and RNA

TMV has 16⅓ protein subunits per turn of the helix and one problem in its assembly is the nucleation of the helix, as a single ring of subunits joined side to side would be readily broken before it had grown to form a small helix. With the growth of a two-layer aggregate (Fig. 1) this problem would not occur as a subunit in either layer could bond to two subunits in the other layer as well as to its neighbours in the same layer, to give a relatively strong, cross-strutted structure. It has also been seen, from the effect of the *p*H drop, that a disk is capable of being transformed into a small helix. In the relevant biological process this is brought about by interaction with the viral RNA rather than by protonation[6]. This interaction occurs between a special sequence of about 50 nucleotides at the 5′-hydroxyl end of the TMV RNA (ref. 6) and two protein disks[9], possibly as shown in Fig. 2a. After the disks have formed short helices, entrapping the first turn of the RNA (Fig. 2b), the initiation is complete and growth can ensue. In general, growth will occur with the RNA protruding from one end of the growing nucleoprotein helix, and the first step will be the interaction of this with a further protein disk which dislocates to become helical and "unrolls" onto the top of the nucleoprotein helix to enclose one turn of the RNA (Fig. 2c). A further turn of the RNA can be enclosed by the second turn of the protein helix by intercalation through the "ruck" which is formed at the end of the first turn, where the RNA protrudes sideways (Fig. 2d).

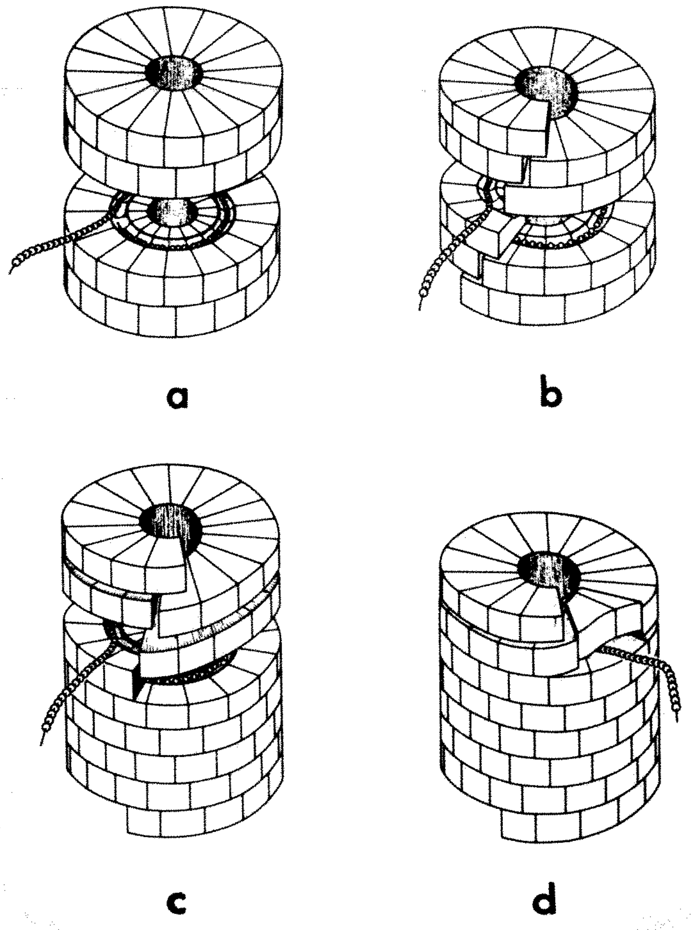

Fig. 2 Model for TMV assembly from disks and RNA[9]. Initiation—a: 5′-hydroxyl end of TMV RNA interacts with two disks; b: disks dislocate to form short helices enclosing end of RNA. Growth—c: dislocated disk "unrolls" to entrap turn of RNA; d: second turn of RNA intercalates through "ruck" formed at end of first turn of helix.

Because of the special nature of the initiation reaction it is very fast and the subsequent growth is relatively slow, unlike most polymerization reactions where the initiation is the slow step. The rate limiting step of the TMV assembly is the actual rearrangement of the protein subunits from the disk into the nucleoprotein helix and is fast enough for the whole assembly to be complete within a few minutes.

General Remarks

The possible role of the disks in nucleation of TMV assembly was foreseen[6] and, indeed, provided the motive for our early experiments with disks and the RNA, but although in hindsight the continued growth with disks as the protein source has several advantages, it was completely unexpected since everyone expected that the virus would grow by adding single subunits at the end of the growing helix, rather like crystal growth along a screw dislocation. The problem of helix initiation has already been discussed and the biological solution for this, using two disks, confers a high degree of selectivity for its homologous RNA onto the protein. This comes about because each protein subunit interacts with three nucleotides in the RNA, and hence 51 nucelotides in all are involved in a single turn of the nucleoprotein helix. In the initiation step these nucleotides bring about the transition of two disks into helix, involving 68 protein subunits, and this apparently requires an especially favourable interaction. By contrast, the use of disks for the further growth will allow even unfavourable nucleotide sequences to interact and to be coated, as the cooperative transition of the protein subunits will result in the favourable interaction nearby overcoming the local unfavourable effect.

Although the formation of disks is slow, taking several hours at normal protein concentrations, these could be formed before the RNA is synthesized and then be available to coat and protect it very rapidly in the plant cell. The optimum conditions for the formation of disks (*p*H 7, ionic strength about 0.1) are about those which might be expected in the cytoplasm of a tobacco plant cell, as must be the case if this mechanism is the true biological one.

Clearly it would be a disaster for the virus if its protein alone could form a stable structure over a wide range of conditions, and so not be available to interact with the viral RNA. The role of the polymorphism of the protein is to prevent the occurrence of this disaster, so that instead of being an adventitious and bothersome feature it is now seen to be the controlling factor for the rapid and successful growth of the virus. This polymorphism is itself controlled by a negative switch which prevents the very stable helix being the dominant form of the protein alone over all moderate conditions, but which can be switched on by the viral RNA to give just this stable product as the virus.

Vintage Year for Tumour Virology

JOHN TOOZE

REVIEWING the results of a year's work in an area of research as active as tumour virology is an invidious as well as a difficult task, for with such a wealth of new information choice is nothing short of embarrassing and sins of omission are all too easy to commit. But no one would, I believe, argue against giving pride of place to reverse transcriptase, the enzyme which Temin and Mizutani and Baltimore (*Nature*, **226**, 1209, 1211; 1970) simultaneously discovered in the particles of four animal and avian tumour viruses, for the significance of the discovery of this enzyme extends far beyond tumour virology. Reverse transcriptase is, of course, the enzyme which can use the single stranded RNA genomes of RNA tumour viruses as templates for the synthesis of first an RNA.DNA hybrid and then a double stranded DNA.

With so many research groups now aboard the bandwagon, it is hard to believe that the enzyme was discovered less than eighteen months ago. It is perhaps even harder to believe that its existence was predicted by Temin as long ago as 1964, when he speculated about the way in which RNA tumour viruses transform cells which have DNA genomes. Temin argued that to become stably associated with the genome of a cell, and to maintain the cell in a transformed or malignant state, the RNA genome of a tumour virus must be transcribed into a double stranded DNA molecule, which he called the provirus. Once the DNA provirus carrying the genes which cause transformation had been made, it could integrate into the cellular genome and be inherited along with the cellular chromosomes. Indirect evidence suggested that transformation by RNA tumour viruses depends on DNA metabolism rather than RNA metabolism and the discovery of reverse transcriptase, an enzyme with the necessary capability, conclusively vindicated Temin's heterodox ideas; it also, of course, provided countless of his colleagues with new research programmes.

Within weeks of the announcement of the discovery of reverse transcriptase, Spiegelman and his colleagues had screened as many different sorts of tumour viruses as they could lay their hands on and had found the activity in all of them (*Nature*, **227**, 563; 1970); today the tally exceeds thirty. Moreover, two viruses—visna virus, which causes a slowly progressing neurological disorder in sheep, and progressive pneumonia virus, which causes a slowly evolving disease of sheep lung have been shown not only to contain reverse transcriptase but also to possess previously unsuspected oncogenic potential; they transform cells *in vitro* (Takemoto and Stone, *J. Virol.*, **7**, 770; 1971). In short, reverse transcriptase as Temin and Baltimore defined the enzyme, that is an enzyme which can use natural single stranded RNA as a template for the synthesis of double stranded DNA, has been found in every RNA tumour virus so far examined.

Tumour virus genomes are not the simplest of RNAs to work with and not surprisingly, Temin (*Nature*, **228**, 424; 1970) and Spiegelman (*Nature*, **228**, 430; 1970) and their colleagues, and other groups, soon began using as templates for reverse transcriptase synthetic RNAs, DNAs and hybrids of RNA and DNA which have a simple and known base composition. Some of these synthetic templates were discovered to have another very great advantage; they were used by the enzyme more efficiently, by almost two orders of magnitude, than the viral genome. For a few weeks if not months this finding caused considerable excitement, for with such very efficient templates for reverse transcriptase at hand it seemed reasonable to hope to detect the enzyme in human cancer cells, supposing they had been transformed by putative human cancer viruses. And sure enough, several groups, for example Gallo and his colleagues (*Nature*, **228**, 927; 1970), found enzyme activities in human leukaemic cells which could use synthetic nucleic acids as templates for the synthesis of DNA; transiently the way seemed open to tracking down human cancer viruses by following the reverse transcriptase footprints they had so obligingly left behind them.

But the bubble soon burst. For although human cancer cells undoubtedly contain a DNA polymerase activity which can be programmed by synthetic double stranded RNAs and hybrids of RNA and DNA, it soon became apparent that such activities are by no means restricted to cancer cells; they are present in normal cells. Todaro and his colleagues, for example, have not only shown that (*Nature*, **229**, 318; 1971), but, using mouse 3T3 cells infected with mouse leukaemia virus, they have separated the reverse transcriptase specified by the virus from the cellular enzyme which can be programmed by synthetic hybrids to make DNA of RNA and DNA (*Nature New Biology*, **231**, 163; 1971). The salutary lesson of this episode was simply that synthetic nucleic acids are not specific templates for reverse transcriptase; they are most useful for characterizing the enzyme once its existence in a cell or virus has been proven in experiments with its natural RNA template, but synthetic nucleic acids cannot be used to establish the enzyme's existence.

Human Cancer Virus

This particular exploitation of reverse transcriptase in the search for human cancer viruses thus ended abruptly in disillusionment. More recently, however, Moore and his colleagues (*Nature*, **229**, 611; 1971) have detected a virus in samples of human milk which in structure closely resembles mouse mammary tumour virus. This murine virus causes mammary cancer in mice and its existence inspired Moore *et al.* to search for a human counterpart. The human milk virus they found seems to be more prevalent in families or populations with a particularly high incidence of breast cancer; moreover, it contains reverse transcriptase which can use as template the endogenous single stranded RNA genome, as Schlom *et al.* have shown (*Nature*, **231**, 97; 1971). Human milk virus is, therefore, the most likely candidate for the distinction of being the first human cancer virus to be identified.

The central role of a reverse transcriptase activity in Temin's provirus hypothesis has been touched on briefly (see above). But what experimental evidence is there to prove that the reverse transcriptase which everyone is assaying in animal tumour virus particles plays any role in the process of transformation ? As more information about the properties of this enzyme and the drugs which inhibit it is being accumulated a trickle of circumstantial evidence which implicates reverse transcriptase in transformation is appearing. Streptovaricins, for example, which block reverse transcriptase also, according to Brockman and his colleagues, prevent the transformation of mouse fibroblasts by mouse sarcoma virus. Furthermore, streptovaricins delay the induction of leukaemia in mice by murine leukaemia virus. Such indirect evidence, however, can always be interpreted in more than one way and the experiments Hanafusa's group reported (*Virology*, **43**, 313; 1971) provide more convincing evidence of the role of reverse transcriptase in transformation. Before the enzyme had been discovered, his group had isolated a variant of Rous sarcoma virus which appeared to be completely uninfectious and, unlike wild type virus, failed to transform chick fibroblasts. After the discovery of reverse transcriptase Hanafusa *et al.* tested their variant and found it lacked activity. The obvious conclusion is that the variant carries a mutation which inactivates reverse transcriptase and renders the virus uninfectious.

To bolster this interpretation of the properties of their variant, they infected chick fibroblasts with the uninfectious sarcoma virus and an avian leukaemia virus which can replicate in these cells but does not transform them. After such double infections the fibroblasts were transformed and yielded progeny sarcoma virus capable of transforming other fibroblasts. However, the fibroblasts transformed by these progeny sarcoma viruses yielded not infectious progeny virus but uninfectious virus identical to the original variant. The most plausible explanation of these results is as follows: the variant lacks reverse transcriptase and as a result is uninfectious and unable to transform; in the presence of an avian leukaemia virus the sarcoma virus genome can use the reverse transcriptase specified by the leukaemia virus and can as a result transform cells; the progeny sarcoma virus particles produced by cells infected with these two viruses are infectious and transforming because they can pick up reverse transcriptase specified by the leukaemia virus; the cells transformed by the progeny sarcoma viruses carrying the leukaemia virus enzyme cannot yield infectious, transforming progeny, however, because the sarcoma virus genome cannot specify its own reverse transcriptase.

These experiments appear, therefore, to prove that reverse transcriptase is essential for establishing transformation, just as the provirus hypothesis of Temin predicts, and they also indicate that once a cell has been transformed by a provirus reverse transcriptase is not essential for the maintenance of transformation. Of course, if transformation depends on the integration of provirus DNA, made by reverse transcriptase, into the host genome several other enzymes must be involved in the process. The two nucleases and the DNA ligase which Temin's group have detected in tumour viruses, in addition to the transcriptase (*Nature New Biology*, **230**, 232; 1971), may be there to accomplish the recombination of provirus and host DNA.

While Hanafusa's experiments indicate that reverse transcriptase is required only during the first step of transformation, Martin (*Nature*, **227**, 1021; 1970) has reported the isolation of a mutant strain of Rous sarcoma virus which carries a lesion in a viral gene, the product of which is required continuously to keep the cell in a fully transformed state. Martin exposed Rous sarcoma virus to nitrosoguanidine and then screened the mutagenized stocks for viruses which transform chick fibroblasts at 35° C but fail to transform cells at 41° C. One of the mutants he has isolated has these properties: cells transformed by the virus at 35° C have all the properties of typical transformed cells; when, however, the temperature of the cultures is raised to 41° C the cells rapidly assume many of the characteristics of untransformed cells growing in culture. If the temperature is lowered again to 35° C the cells once more appear to be transformed. Clearly this mutant carries a temperature sensitive lesion in a viral gene which must be continuously expressed to maintain transformation *in vitro*.

Whether or not Martin can show that this mutation also affects the growth of sarcomas induced in chicks in the same way in which it affects the transformation of cells in culture remains to be seen. If he can prove that the mutant affects tumours *in vivo* the identification of the product the mutated gene specifies should answer many of the outstanding questions of tumour biology.

Oncogenes

Although RNA tumour viruses and some DNA viruses (see below) are able to infect and transform susceptible cells in culture and induce tumours in susceptible animals, very few natural cancers have the epidemiological characteristics of infectious diseases. For this reason Huebner and Todaro postulated that genes capable of causing malignant transformation, so called oncogenes, are part and parcel of every animal's genetic make-up. Carcinogens, they envisage, act by switching on oncogenes or in the case of tumour viruses by doing this and also introducing more copies of oncogenes into a cell. Such an all embracing hypothesis is hard to test rigorously but Hanafusa *et al.* (*Proc. US Nat. Acad. Sci.*, **67**, 1797; 1970), Vogt and Früs (Second Lepetit Colloquium, 1970) and Weiss during the past year have provided perhaps the most convincing evidence so far to support the oncogene story. In short, they have been able to isolate an avian leukaemia-type virus (it has yet to be proven that this virus can induce leukaemia) from the cells of apparently healthy chick embryos and Weiss has even induced the production of this virus in the cells of wild Malayan jungle fowl. These observations suggest that the cells of all chickens, irrespective of whether or not the birds are destined to develop leukaemia, have the genetic potential to specify an avian leukaemia virus.

Inevitably, RNA tumour virologists in their first flush of enthusiasm after the discovery of reverse transcriptase have stolen most of the limelight from their colleagues working with the DNA tumour viruses, which outside the laboratory are unlikely to be important carcinogens. But it would be mischievous to imply that the DNA tumour virologists have been gathering moss. Both Eckhart and Dulbecco (*Proc. US Nat. Acad. Sci.*, **67**, 1775; 1970) and Benjamin (*Proc. US Nat. Acad. Sci.*, **67**, 394; 1970), for example, have characterized conditional lethal and host range mutants of polyoma virus which carry lesions in a gene or genes, the product(s) of which are required continuously to maintain a cell in the transformed state. These mutants are equivalent to that of Rous sarcoma virus isolated by Martin (see earlier) and it is now clear that the integration of a tumour virus genome into the genome of a host cell is not sufficient although it appears to be necessary to maintain transformation. And the recent experiments of Wall and Darnell (*Nature New Biology*, **232**, 73; 1971) dispel any remaining doubts about the integration of polyoma virus DNA into host cell DNA. For they have shown that in polyoma transformants messenger RNA molecules are made which contain both cellular and viral base sequences in the same molecule.

But perhaps the greatest stir among DNA tumour virologists during the past twelve months has stemmed from experiments with agglutinins or lectins, glycoproteins which are obtained from plant seeds and which cause cells to clump or agglutinate. It now seems clear that although both normal cells and cells transformed by DNA tumour viruses and some chemical carcinogens bind more or less the same amount of any given agglutinin (Ozanne and Sambrook, Livingstone and Cline, *Nature New Biology*, **232**, 155, 156; 1971) the transformed cells are more readily agglutinated than normal cells. Moreover, cells transformed by the temperature sensitive mutant Eckhart has characterized behave like normal cells when grown at the non-permissive temperature. These findings indicate that the surface of a transformed cell differs from that of its untransformed counterpart and that this change is probably controlled by the transforming gene of the virus. Changes in the cell surface on transformation no doubt account for many of the characteristic properties of transformed cells including their failure to respond to contact inhibition of growth when maintained in culture. And *in vivo* the ability of cancer cells to metastasize no doubt stems from some change in the cell surface. Clearly much future research in tumour virology will be concentrated on the chemistry and structure of the surface of untransformed and transformed cells as well as on reverse transcriptase, the genetics of tumour viruses and the search for human tumour viruses.

Glaciation and the Stones of Stonehenge

G. A. KELLAWAY
Institute of Geological Sciences, 5 Princes Gate, London SW7

More geological evidence can now be brought to bear on the problem of the origin of Stonehenge. Spreading ice sheets rather than human activity could have brought the rocks to Salisbury Plain.

FOLLOWING the discovery of glacial deposits in north Somerset[1], the search for other evidence of regional glaciation has continued. In 1969, shortly before the M5 motorway sections at Clevedon became available, Dr A. Whittaker of the Institute of Geological Sciences found abundant fragments of white Chalk scattered on the steep landslipped slopes of Brent Knoll, Somerset. The Knoll is an isolated hill composed chiefly of Jurassic clay rising out of the coastal marshes between the Mendips and the mouth of the River Parrett and attaining an altitude of 457 feet (140 m) above O.D. This was the first intimation that Cretaceous Chalk might exist in the Drift deposits of Somerset. The source of the Chalk fragments is still uncertain. However, in the light of subsequent developments it seems that they may have been derived from submarine outcrops, or from outliers of Chalk (now perhaps destroyed), the material having been deposited by an ice sheet entering Somerset from the south or west.

Late in the summer of 1970, I found Chalk-bearing Drift deposits at Holwell near Nunney [ST 72554523] in the eastern Mendips where temporary exposures were seen while ground was being cleared for a new quarry. Here reddish brown sandy clay up to 3–4 feet (1 m) thick rests on Jurassic limestone (Inferior Oolite). The deposit is thin and patchy and has been partly decalcified, but the deeper pockets contain rounded and subangular fragments of hard white Chalk thought by Mr C. Wood to have come from the lower or middle part of the formation. Flint, chert, sandstone, quartzite and Carboniferous and Jurassic limestone pebbles are present, suggesting that the material is a relict till.

These and other glacial deposits situated on limestone uplands at the eastern margin of the Mendips at an altitude of about 500 feet (152 m) above O.D., lie in the proximity of gorge-like melt-water channels transecting the Mendip ridge at Nunney and East Cranmore. Their discovery at once suggests that ice could have blocked the western approaches to the Vale of Pewsey and the low lying ground described by F. W. Harmer[2] as "Lake Trowbridge". He believed that water from this lake was responsible for the downcutting of the Avon Gorge at Clifton.

Spread of Ice

During the most recent glaciation (Devensian, or Weichsel) ice from the uplands of South Wales reached the Vale of Glamorgan locally, but the main mass of ice in the Irish Sea did not cross the Pembrokeshire peninsula. It may, however, have extended somewhat further south in St George's Channel than was formerly supposed[3]. Most of the lowlands of South Wales and the greater part of the west and south of England, with the possible exception of Dartmoor and some other high ground, were unglaciated. Winter snowfall may have been heavy in the south-west, permafrost more strongly developed in the south-east of England. The Devensian ice of the Midlands seems to have come no further south than Wolverhampton, thus the greater part of the lower Severn Valley and the Cotswolds were not glaciated. Thick deposits of Head formed in Devon and Cornwall, the Mendips and Cotswolds, and were represented in Wessex and south-eastern England by the familiar "Coombe Rock".

Conditions during the two glaciations preceding the Devensian were very different. The penultimate (Wolstonian, or Saale) glaciation seems to have affected most, if not all, of South Wales[4] and in the deep valleys of the Pennant Sandstone uplands it is difficult to make a distinction between Devensian and Wolstonian glacial features and deposits[5]. In Pembrokeshire, the Vale of Glamorgan and Somerset the effects of the Wolstonian Glaciation are however recognizable.

Using information accumulated during the past decade the position of the main streams of ice moving eastwards along the Bristol Channel during the Wolstonian Glaciation can now be outlined. In the far west Lundy Island is said to have been overriden by the Wolstonian ice sheet[6], and glacial deposits were laid down at Fremington and Barnstaple[7]. Further east the great flow of ice which passed over Pembrokeshire was constricted as it moved up channel, confined on the north by the high ground of the South Wales Coalfield[5] and on the south by Exmoor and the Brendon Hills. Crossing the Severn Estuary, one arm of the ice moved up the broad Flax Bourton valley leading to Bristol[1]. Another stream, after dividing round the western Mendips, moved eastwards, crossed the lowlands of Somerset and invaded West Wiltshire. The northern part of the ice flow carried rocks which were derived principally from the South Wales Coalfield and the

Severn Estuary. In the central region erratics which can be matched with rocks from the Lake District, North and South Wales are found. In the south the erratics come mostly from Devon and West Somerset. Considerable quantities of marine and estuarine material torn or scooped up from the exposed floor of the Bristol Channel were carried into Central Somerset and the Clevedon area. Cretaceous flint and chert is abundant in almost all the glacial deposits, and has found its way into the younger raised beach deposits and the Devensian Head. Unlike the much older "Anglian" or Elster Glaciation the Wolstonian ice appears to have introduced no sarsen stones, and where this glaciation was strongest the Tertiary sarsen erratics carried by the older "Anglian" ice have been cleared away or thrust to one side.

"Anglian" Glaciation

The question remains, however, whether the glaciation, which seems to predate the so called "25-foot" raised beach of the Weston-super-Mare district and may therefore be comparable in age with the Chalky Boulder Clay glaciation of the Vale of Moreton, was responsible for the introduction of erratics to Salisbury Plain. The Wolstonian ice would have been capable of conveying Pembrokeshire material to the region east of the Severn Estuary and Bristol Channel. There are, however, indications of an older "Anglian" glaciation of the West of England and Bristol Channel which was much more extensive and carried very large Scottish erratics weighing as much as 50 tons[8]. This glaciation was probably responsible for the introduction of Welsh erratics to Salisbury Plain (Fig. 2). It equates with the ancient Plateau Gravel or "Northern Drift" ice sheet which carried Bunter pebbles and other northern erratics into the Cotswolds and the Upper Thames Valley and which preceded the formation of the Hanborough Terrace of the Upper Thames and Evenlode Valleys[9]. The magnitude of the glaciation can be judged from the fact that the upper surface of the ice-sheet in the vicinity of Cheltenham stood at well over 1,000 feet (305 m) above present sea level. One of the first comprehensive studies of the problems presented by the fragmentary record of this great glaciation, of which little evidence has survived further north, was made by Sandford[10,11].

The "Anglian" glaciation of the eastern part of the English Channel is thought to be of the same age as the "Anglian" glaciation of Devon and Cornwall where the presence of big "foreign" erratics has been attributed to the action of "coastal ice". The situation of the big erratics found at Croyde in North Devon cannot be explained in this way without assuming that the sea level was as high or higher than at present; this during a major glaciation. As Taylor has pointed out[12,13], the presence on the north coast of Devon of rocks from South Devon can hardly be accounted for by the drifting ice theory without arousing incredulity.

The name "Anglian" is in many ways unsuitable because of its link with the East Anglian succession. It should therefore be clearly understood that, as used in this account, the term refers to the ice sheet which invaded the coastal region of Hampshire and Sussex from the west carrying sarsens and big "foreign" erratics[14,21]. Erratic pebbles from these or comparable glacial deposits were later incorporated in the marine gravels of the Slindon (or 100-foot) raised beach of West Sussex[15]. Others found their way into the younger solifluction and beach deposits of the coastal plain.

The very low sea level accompanying the "Anglian" glaciation of southern England and the English Channel was therefore separated by the high Slindon (Tyrrhenian) sea level from that of the Wolstonian (Saale) glaciation. During the period of falling sea level marking the retreat of the shore-line from the 100–300 foot level intensive piping and disturbance of the Slindon raised beach and the formation of very thick solifluction deposits (the Main Coombe Rock of Sussex) took place.

It is generally considered, however, that the ice of the Wolstonian glaciation did not extend into the central and eastern parts of southern England. Salisbury Plain, though dissected by melt-water from the Wolstonian ice, does not seem to have been covered by an ice sheet at this time. The removal of the Clay-with-flints which was noted by Reid[16], probably took place during the "Anglian" glaciation. The detailed movements of the various ice masses invading southern England during this glaciation are as yet unknown. They may well have been complex, and the directions shown in Figs. 1 and 2 should be regarded as only an approximation.

It seems likely that the older highly cryoturbated Plateau Gravels of the Hampshire Basin represent disturbed glacial outwash from the "Anglian" ice since they are composed of material derived from the Clay-with-flints, and the local Mesozoic and Tertiary rocks. Small and medium-sized sarsen boulders are present, and Palaeozoic rocks also occur particularly in the western districts.

Irish Sea Erratics

Turning to the question of the known eastern limit of Irish Sea erratics, pebbles of porphyritic igneous rocks together with flint, chert and "flinty slate" were found in the nineteenth century on Flat Holm island in the Bristol Channel[17]. The Geological Survey collection includes a fragment of a "soda-granite" from the same locality, presumably part of a pebble of Welsh origin. The desirability of re-examining Flat and Steep Holm has been evident for some time and in May 1971 I paid a brief visit to the islands in company with Mr Brian Hawkins of Bristol University and Dr Brian Kelk of the Institute of Geological Sciences.

On the south side of Flat Holm the storm beaches are composed almost entirely of local Carboniferous Limestone (Goblin Combe Oolite and Clifton Down Mudstone) but on the north side the limestone pebbles are mixed with Chalk flint, greensand chert, Old Red Sandstone and a wide range of igneous and metamorphic rocks which have been identified by Mr R. K. Harrison and seem to have been derived from South Wales, North Wales and the Lake District. The erratic tracks fit with the evidence from South Wales where Bowen[4] has recently summarized the work of Griffiths[18] demonstrating the dispersal of Pembrokeshire and other rocks carried by ice from the Irish Sea, probably in Wolstonian times. On the other hand, the Flat Holm beach material includes very little rock from the mainland coasts and the most likely explanation is that the pebbles are derived from a submerged deposit of till, probably lying off the north coast of the island. Further discussion is postponed until this has been located and other reported occurrences of erratics have been investigated.

Here it may be useful to observe that reddish brown till with Chalk flints, greensand chert and rocks from South Wales was found in 1970 at or below sea level at Kenn near Clevedon, though in this case the glacial deposits are buried by Holocene mud[1]. Other residual masses of glacial sand and gravel ("Burtle Beds") rise out of the marshes in central Somerset at Catcott Burtle, Westonzoyland and Othery[19]. In these outwash deposits, previously described as marine, the remains of marine, estuarine and freshwater organisms as well as the bones of land animals occur. The associated erratics are derived chiefly from West Somerset and North Devon. They include Devonian or Old Red Sandstone, Carboniferous, Bunter and Jurassic rocks, Cretaceous chert and flint. These are associated with pellets of soft red and green Triassic mudstone, some mixed with marine shells and remoulded in ice, others, lumps which may have been rounded while in a frozen condition. At least one mega-erratic is thought to have existed in the Westonzoyland area[20]. This was known as the "Devil's Upping Stock". Unfortunately it was cut up for ornamental stone and its petrological affinities are therefore unknown.

Scattered on the Dorset, Marlborough and Berkshire downs are isolated groups of Tertiary sandstone erratics known as sarsens. The name is probably derived from the Anglo-Saxon *sar* (troublesome) and *stan* (a stone), and, as Chatwin[21] has pointed out, it is significant that a farming people should have paid particular attention to them.

Many differing views have been expressed as to their ultimate source and mode of emplacement. A full discussion of these problems must await more detailed description. For present purposes, however, it may be said that in certain areas, notably Sussex and Somerset, they behave as would any other erratics and are associated locally with erratics of "foreign" rocks which seem to have travelled with them. The Wolstonian ice of the Bristol Channel does not seem to have picked up Tertiary sandstone, possibly because it did not traverse the extensive tracts of submerged Tertiary rocks found in the English Channel and the western approaches. Nor were sarsens carried by the "Northern Drift" ice of the Cotswolds and Severn Valley.

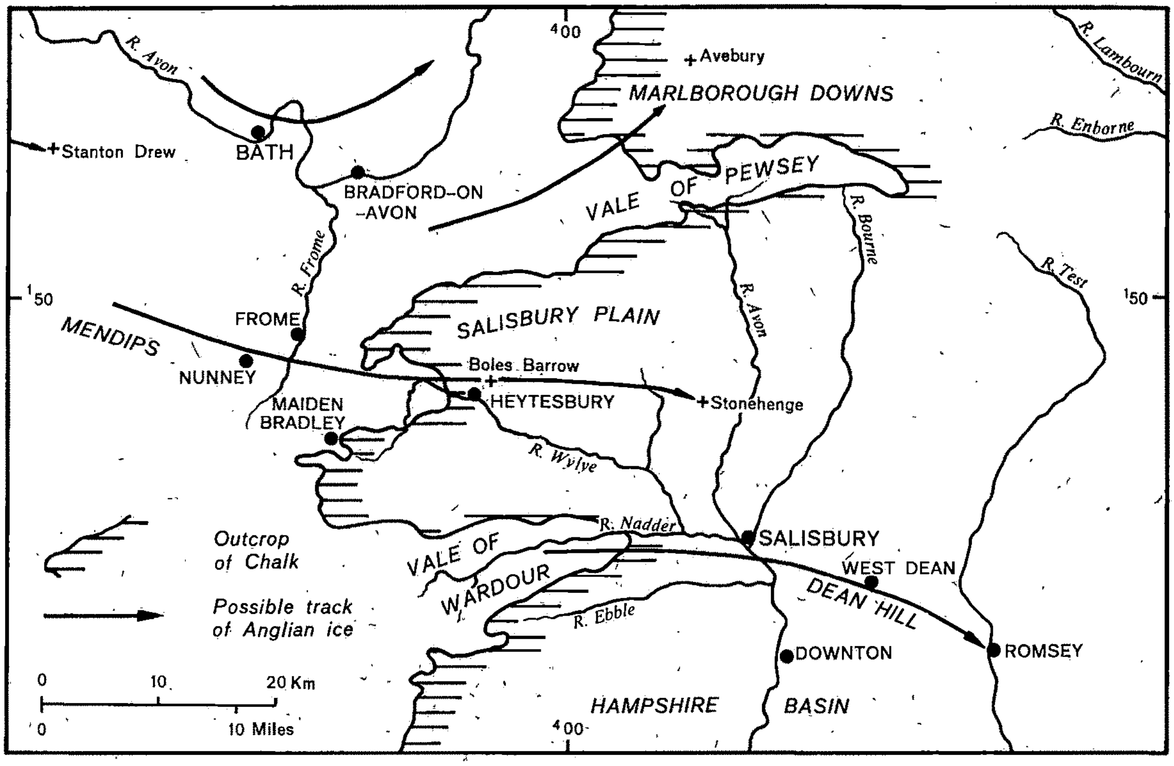

Fig. 1 Sketch map of Salisbury Plain and its environs showing principal localities referred to in the text. Ice entering Wiltshire from the west may subsequently have been deflected by sarsen-bearing ice from the English Channel moving in a SW–NE direction.

South of Bristol and Bath sarsen erratics are found on high ground in the eastern Mendips and Broadfield Down, mostly in areas which were not eroded by the Wolstonian ice. In Sussex, on the other hand, the sarsen erratics were obviously brought in by ice from the English Channel and the most likely sources of the sandstone, which is not found in the local rocks on shore, are the Tertiary formations which are known to cover large areas of the sea floor.

Sarsens and Stonehenge

For the archaeologist the sarsen stones and their origin are matters of particular interest, since the two greatest megalithic monuments in the British Isles, Avebury and Stonehenge, are built wholly or in part of sarsen sandstone. As long as it was believed that the sarsens were the remains of a relict Tertiary sandstone "lowered" into position by the dissolution of the chalk, progress in understanding the distribution of the sarsens and the glaciation of southern England was impeded.

One of the most mysterious features of the great megalithic monument of Stonehenge is the presence of the foreign stones, or "bluestones" as they are popularly described[22]. It has long been known that these are not of local origin and there has been intense speculation about their presence on Salisbury Plain. Since the bluestones of Stonehenge are considered to have come from Pembrokeshire, the discovery of evidence for the glaciation of the region east of the Bristol Channel is clearly of more than local geological significance. H. H. Thomas[23] who was the first to recognize in Pembrokeshire the probable source of the bluestones, believed that there was no valid evidence to support the theory advanced by Judd[24], that they were conveyed to Salisbury Plain by ice. At this time the existence of glacial deposits at Fremington in North Devon had only tentatively been recognized by Maw (1864)[25] and their glacial origin was not generally acknowledged until much later[18,26,27]. On the other hand, the clearly expressed views of Harmer[2] respecting the glacial origin of the gorges of the Bristol Avon were widely ignored or frankly disbelieved by most geologists working in the area. Thomas therefore concluded that ice from the Irish Sea did not reach Devon and Somerset and went on to say that the available evidence "permanently disposes of the idea of glacial transport for the Foreign Stones of Stonehenge".

The effect of this pronouncement on archaeology and, indirectly, on English glacial geology has been considerable. H. H. Thomas explained the presence of the foreign stones on Salisbury Plain and the wide variety of rocks represented among the bluestones by suggesting that they were originally erratics gathered up locally and used in the construction of a great stone circle which he thought might have been built at

Cil-maen-llwyd on the south-eastern slopes of the Preseli mountains[23]. In this way he accounted for the presence of relatively soft sheared volcanic rocks which would not otherwise have been used for building, particularly where hard dolerite and rhyolite are freely available as they are at Mynydd Preseli. According to this theory the stones were subsequently removed from this "venerated stone circle" and conveyed by its votaries to Stonehenge. The archaeological evidence for the "venerated stone circle" has since been discredited[28,22]; but belief in the human transport of the stones has persisted, though the theory of overland transport preferred by H. H. Thomas has been replaced by carriage by water.

One outstanding item in this problem is the Altar Stone, shown by Thomas to have been derived originally from the Senni Beds of Breconshire or, alternatively, from the Cosheston Sandstone of southern Pembrokeshire. Even if we suppose that all the Old Red Sandstone material found at Stonehenge came from South Pembrokeshire, there is still no means of establishing Mill Bay or Milford Haven as the immediate source of the material used at Stonehenge. Not only does the Old Red Sandstone of south Pembrokeshire cover a fairly large area on land, it also extends beneath the sea and it has long been known that the whole region has been strongly glaciated. It may be that Neolithic man picked up a 7 ton boulder of Cosheston Sandstone on the foreshore of Milford Haven. On the other hand, ice could have quarried the bedrock or picked up a boulder from a very much wider area, and deposited it anywhere between south Pembrokeshire and Salisbury Plain. It is certain that neither the Altar Stone nor some of the other sedimentary rocks recognized by Judd[17] at Stonehenge came from the Preseli Mountains. As Judd pointed out, many of the Palaeozoic rocks found at Stonehenge would have been too soft or fissile to have been of any value as a building material. The inference is plain. Even if the hard igneous rocks were worth transporting to Stonehenge, the softer stones have still to be accounted for, and glacial action is the only reasonable solution.

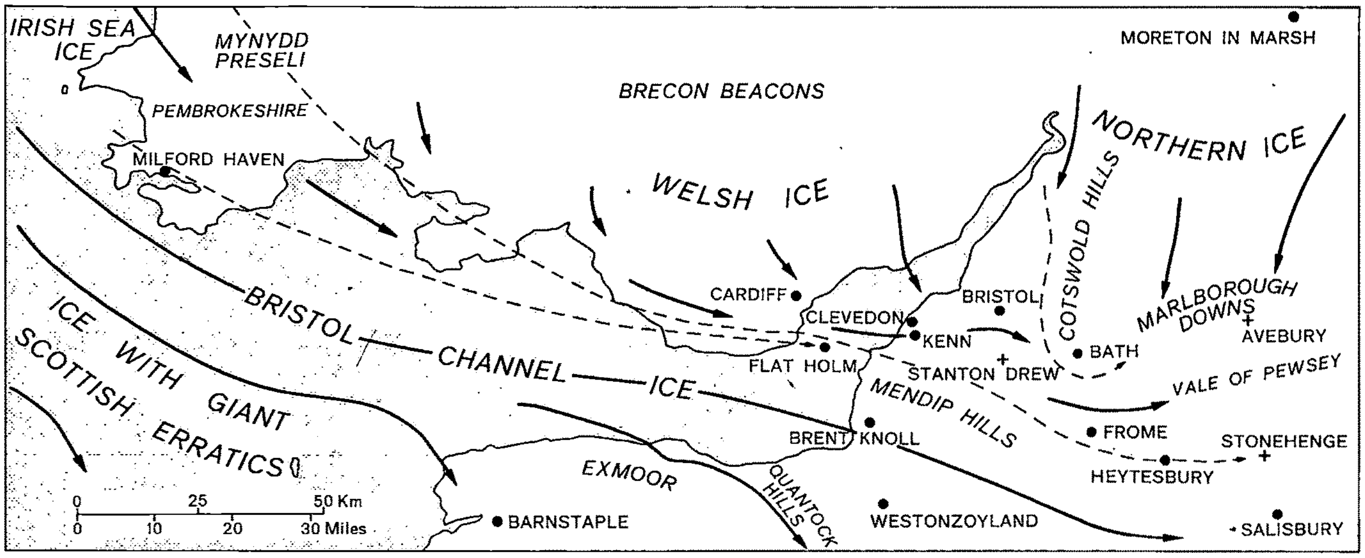

Fig. 2 Bristol Channel region showing generalized erratic "tracks" and inferred direction of flow of the "Anglian" (Elster) ice. Exmoor may have formed a small centre of local ice accumulation, the Mendip and Cotswold Hills were largely overridden at the height of the glaciation. The northern limit of the sarsen erratics is given roughly by a line joining the southern end of the Quantock Hills, Stanton Drew, Bath and the northern edge of the Marlborough Downs.

Apart from the bluestones at Stonehenge, only two other large pieces of igneous rock from Salisbury Plain are known to exist. Both are preserved in Salisbury Museum. One is a boulder weighing about 9 ton found in company with sarsen stones in the Neolithic long barrow known as Boles Barrow near Heytesbury [ST 94214677]. The other is a smaller stone from Lake, south of Amesbury in the valley of the Salisbury Avon. Both appear to be petrologically similar to the dolerites from Mynydd Preseli and those at Stonehenge. The stone from Lake may, however, be a piece detached from one of the Stonehenge bluestones in comparatively recent times and for present purposes is best ignored.

If the bluestones of Stonehenge were conveyed in ice from Pembrokeshire it might reasonably be expected that some ice-scratched or polished erratics would have been found in Wiltshire. Many of the bluestones used at Stonehenge have been dressed or shaped by hand, others show rough or matt surfaces which convey no useful information beyond the fact that they have undergone some weathering. The Boles Barrow stone does appear to retain part of its original surface on which the harder crystalline knots or patches have been faceted. This may be a relic of glacial smoothing, but much of the polish on the stone is due to handling.

The relative age of Boles Barrow and Stonehenge is said to be uncertain, though the former is attributed to the Windmill Hill culture and Stonehenge to the Beaker culture. Archaeological evidence shows that the foreign stones were certainly on Salisbury Plain in Neolithic times[29] and that the bluestones of Stonehenge were originally used in the construction of an earlier monument, possibly at the Cursus[30].

Other Means of Transport

Following rejection of the theory of glacial transport, carriage of the stones on boats or rafts by way of the strongly tidal Severn Estuary and Bristol Avon has come to be the most widely accepted hypothesis. Nevertheless the Neolithic and Bronze age rivers differed considerably from those of the present day, and the Bristol Avon has been virtually converted into a man-made channel by centuries of excavation, dredging and control by embarkments, lock gates and weirs. It seems to me questionable whether river transport of such massive stones was practicable above Bathampton in Neolithic times even if the serious navigational hazards of the Severn Estuary and the lower Avon had been surmounted.

Why should the builders of Stonehenge carry lumps of slate, quartzite, greywacke, flagstone, soft-sheared volcanic ash and Old Red Sandstone to Stonehenge when ample supplies of hard dolerite were available at Mynydd Preseli? The strange mixture of stones—Old Red Sandstone, dolerite, rhyolite, volcanic ash, calcareous ash—described by Atkinson[22] from the west side of the bluestone circle, and the presence of Chilmark Stone from the Vale of Wardour in the packing of stone holes, certainly supports Judd and Thomas in their conclusion that the stones were originally erratics. The reasons for thinking that these were collected from a "venerated stone circle" and conveyed overland are, as we have seen, no longer acceptable. The suggestion that Mynydd Preseli was a "sacred mountain" leaves unexplained the use of Cosheston Sandstone and other Old Red Sandstone rocks from unsanctified south Pembrokeshire. Yet, if the stones did not come from one "venerated stone circle" or "sacred mountain" the motives for conveying them 150 miles (241 km) to Stonehenge while ignoring local resources, are incomprehensible. For large masses of suitable stone (Great Oolite Limestone) remain to this day, within 20 miles (32 km) of Stonehenge on the landslipped slopes of the Avon valley between Bathampton and Bradford-on-Avon, the identical defile through which the Pembrokeshire rocks are supposed to have been conveyed by Bronze Age man to Salisbury Plain.

In view of recent developments a re-examination of the Stonehenge rocks has been commenced. Whatever may be the outcome of these investigations there is bound to be an element of doubt about some of the earlier conclusions. While it is true that some or all of the igneous bluestones could well have come from Mynydd Preseli, comparable rocks are known in the Ordovician terrain near Cader Idris[23,31]. There may also be offshore areas of similar Ordovician volcanic and associated intrusive rocks in the Irish Sea and St George's Channel[18].

This does not affect the interpretation of the glacial history since it can be demonstrated that ice flowed out of the Irish Sea into the Bristol Channel carrying rocks from a very wide region. However, it has a critical bearing on the theory of human transport which depends on the material having been derived from a limited area on land. If it could be proved that Neolithic man actually quarried the crop of the spotted dolerite at Carn Meini or worked the frost-shattered debris on Mynydd Preseli the theory of human transport might be credible. No such evidence has been produced. Neolithic flint miners dug shafts and galleries in the chalk in Sussex and East Anglia but their tools, like those used at Stonehenge, were deer horn, bone, flint, sarsen and wood, of little value for quarrying hard massive rocks. In practice, Neolithic man therefore used lumps and boulders, or tabular erratics and slabs that he could split with the aid of fire and water.

Frost-wedged fragments, though not strictly erratics, could also have been used at Stonehenge, but even if this could be established it would not prove transport by human agency, since some of the Stonehenge erratics may well have been broken down *in situ* by frost action on Salisbury Plain.

Archaeological attention has been diverted from the effects of glaciation and concentrated on the petrology of the igneous bluestones in the belief that it is possible in this way to prove that they were conveyed by man directly to Stonehenge. Without questioning the conclusions of Thomas[23] concerning the original source of the igneous bluestones used at Stonehenge, it must be admitted that there are circumstances when the use of specific "indicator rocks" to pinpoint individual localities can be misleading. Of very few rocks can it be said that they are unique and confined to one small area and that no other occurrences may exist on the sea floor or beneath drift deposits on land. Pebbles and fragments may be secondarily derived, glacial erratics can be introduced by an early glaciation and moved again during a later one. Errors in determining provenance are one of the hazards of using erratics but the risks have to be accepted if progress is not to cease

Erratics in Megalithic Monuments

If Stonehenge and Boles Barrow are constructed of, or incorporated, large erratics deposited by the "Anglian" ice, other megalithic monuments in the area glaciated by the "Anglian" and Wolstonian ice may be expected to show similar features. For this reason the stone circles of Stanton Drew and the outlying stones in the Chew valley of north Somerset[32] are an ideal case for investigation. The monument is sited on Triassic marl but local (Triassic) sandstone is present in the vicinity and would have been suitable for quarrying if Neolithic or Bronze age man had been able to do so. Undressed stones up to about 27 tons in weight, but of variable size and shape, have been used at Stanton Drew, none of them of local origin. The monument includes three stone circles, and a group known as The Cove. Some of the outlying stones, including Hautville's Quoit, may or may not have formed part of a structure. Rocks used in the monument or found at the Cove and Hautville's Quoit include silicified and mineralized dolomitic conglomerate from Broadfield Down and the Mendips[33], Old Red Sandstone possibly from Wales or from the Portishead Beds of Blackdown or the Portbury district, Dundry Freestone (Inferior Oolite) and Tertiary sarsen stone. The massive blocks of Dundry Freestone can only have come from the western end of Dundry Hill. The sarsen, which it has not yet been possible to examine petrologically, can be matched by sarsen fragments found on Felton Common [ST 518651] the broad west–east valley crossing Broadfield Down 6.5 miles (10 km) south-west of Bristol. Fragments of sarsen stone at Felton Common were previously mistaken for Rhaetic (which also occurs on Broadfield Down), but the rock contains the characteristic rootholes. Sarsen erratics, presumably introduced by the "Anglian" ice, are not uncommon on high ground south of Bristol. These may not have been over-ridden by the Wolstonian ice sheet.

Tracks of the stones used at Stanton Drew have a strong west–east component and it is noticeable that though Triassic sandstones are present locally and hard Coal Measures sandstones crop out about 1.5 miles (2.4 km) east of Stanton Drew, neither of these rocks has been used in the construction of the megalithic monument. The situation of the stones of Stanton Drew is entirely consistent with the possible site of a moraine upstream of the Chew gorge at Pensford [ST 617637]. The latter may have operated for a time as a spillway from a glacial lake covering the upper part of the Chew valley, including the area of the present reservoir. In this instance the erratics were probably introduced by the "Anglian" ice, final emplacement having taken place in Wolstonian times. Some of these large tabular erratics, notably the dolomitic conglomerate of The Cove, could have been in the form of giant slabs which were later broken up, either by natural processes or by man.

Other large isolated stones or groups of stones formerly existing in otherwise stoneless areas of Wessex have been broken up for hard core or destroyed as pagan monuments. Some of these acts of vandalism have been inscribed but the only record of the existence of other vanished stones is to be found in the local place names or in folklore[34]. The surviving greywethers in the downlands of Wessex and Sussex, the Mendips and west of England, probably give only a faint impression of the former extent of the boulder strewn surfaces.

Many erratics are almost certainly enclosed in chambered long barrows and similar structures and a comprehensive study of these rocks might yield valuable evidence bearing on the direction of "Anglian" ice movements. Grinsell[32] has estimated that there are about 200 long barrows in Wessex alone. Not all of them are chambered, and the average weight of stone per barrow can only be guessed, but if 100 long barrows contain an average of only 50 tons a piece it would mean that 5,000 tons of medium–large erratics could be included within them. This would still leave uncounted the enormous quantities of stone originally used in sites such as Avebury where some of the sarsen erratics weigh up to 40 tons and one of 90 tons formerly existed.

Erratic boulders of up to 350 tons are said to exist in the Carnac area of south Brittany and giant erratics and glacial rafts of huge dimensions are found in Britain and many parts of the world. Nobody knows the original size of the Stonehenge sarsen erratics before they were split and trimmed, but their stratigraphy suggests that a number of them may have formed parts of one or more giant slabs stranded somewhere in the vicinity of the monument. As an example demonstrating the size which can be attained by such glacial erratics we may refer to the immense mass of tabular Silurian limestone found in Warren County, Ohio. This slab, though only 5 feet (1.5 m) thick has a surface area of 20,000 square feet (1,858 m^2)[35]. Even larger erratics consisting solely of quartzite are found in a boulder train near Calgary, Alberta[36]. Beneath such huge tabular masses, till, pebbles and boulders may be preserved even when the surrounding areas have been cleared by erosion. This may well be the explanation of the survival at Stonehenge of lumps of relatively soft volcanic rock such as the ones represented only by stumps in the bluestone circle. Soft rocks, or compact but frost-susceptible erratics partly buried in glacially disturbed Chalk or chalky till and preserved from erosion beneath huge flat-lying frost-resistant sarsen stones, may have been unearthed by Neolithic or Bronze age man when building his monuments. Some of these smaller erratics may have appeared to be hard enough to use for building and may have survived for a time before breaking down under the influence of frost and rain. Without some such explanation it is difficult to see why the rocks should ever have been used at all, much less carted from Pembrokeshire and then trimmed on site with all the attendant risk of wasting stone.

It has also been claimed that the sarsens of Stonehenge were dragged overland from Avebury, but there is no geological evidence to support this. Nor does it seem at all likely that they were moved on frozen ground in late Neolithic or early Bronze age times[37], when the climate may have been warmer than at the present day.

There seems to be a close correlation between the distribution of long barrows in Wessex (ref. 32, Map 1) and the downland areas now thought to have been invaded by the vast but ancient "Anglian" ice sheet. For example, the presence of Jurassic limestone built into the chambered West Kennet Long Barrow [SU 10506775] and other barrows in the Bishop's Cannings valley on Marlborough Downs[32,38] suggests that the Avebury sarsens may have been dumped as part of a moraine at the terminus of a stream of ice moving in an easterly or north-easterly direction (Fig. 1). It is not unreasonable to suppose that the presence of non-local clay found in the centre of some barrows may be the remains of till deposits disturbed during the lifting and erection of erratics.

Much work will be needed on the chambered long barrows before detailed conclusions can be drawn about these movements, and in many areas there is little reliable information as to the nature of the stones used in their construction. It may be no coincidence, however, that the western part of the Marlborough Downs has some of the most characteristically glaciated profiles to be seen in this part of Britain. The moulded outlines, broad U-shaped dry valleys and melt water channels of the downlands are in some respects the most interesting of the glacial features, but their assessment demands more extended treatment than is possible at this stage.

Any calculation of the original quantity of erratic material on Salisbury Plain necessarily ignores the smaller pebbles and fine grained material dissolved, blown, washed away, or moved by solifluction during dissection of the uplands in the two major cold periods following the "Anglian" glaciation. To these later periods belong the valley gravels of the Wylye, Avon, Test and other rivers, and the solifluction streams which concentrated the medium and some of the big sarsens in the dry valleys of the downlands. Only the inertia of the larger erratics and their situation on normally waterless uplands preserved them for the use of Neolithic man.

I thank everybody who has provided information and material, especially Mr Brian Hawkins, Dr Brian Kelk, Mr R. K. Harrison and Mr C. Wood. I also thank Mr H. S. Shortt, Mr C. Bowen and Mr R. S. Newall for help with archaeological problems. The manuscript was edited by Miss E. M. Pyatt.

Was there really a Big Bang?

G. BURBIDGE
University of California, San Diego

The evidence in favour of a big bang cosmology is much less definite than is widely realized, and it is not impossible that we are living in a steady state universe.

In any given field of science, activity has its peaks and its valleys. Many view activity as synonymous with progress. If one judges by the number of papers currently appearing and by the interest of the younger astrophysicists, activity in cosmology is at a peak at present. To the outsider and even to many inside, it looks, at first sight, as though considerable progress has been made in recent years, so that the outline of the way in which the universe has evolved is understood and only the details need to be explained. Is there any justification for this? Those who have read widely in the earlier and more recent cosmological literature, as well as those who rely on North's account[1], are aware that views of cosmology at any epoch are largely determined by the ideas of a few strong individuals, rather than by an objective appraisal of the information available. Today a similar situation prevails, and it is further complicated because we are often trying to use classes of objects to test cosmological theories long before we understand the physics of them.

In my view, modern developments have been influenced by several factors. They include new observational discoveries combined with an extremely simple minded approach to them, a deep seated conviction by many that general relativity is correct in all details, a belief that astronomy has nothing to teach us about fundamental physics, and, last but not least, a deep seated hostility by both observers and theoreticians in the astronomical community toward the steady state theory. Usually this last point is not mentioned in polite society, but it is blatantly obvious in Dingle's remarks[2] while president of the Royal Astronomical Society; it is often apparent in private discussions, and a further manifestation is a complete disregard of the theory when the state of cosmology is reviewed (see, for example, ref. 3).

What are the major scientific events which make up the case for a big bang? They started, of course, with the work of Einstein in 1917. Incidentally, he, as did his contemporaries, took it for granted that the universe in the large is unchanging, that is, he assumed that it is in a steady state. But it was Lemaitre[4,5] and, independently, Friedmann[6] who showed that the Einstein universe is unstable so that, when perturbed in the direction of expansion, it will continue to expand, tending to a de Sitter universe in the limit. Lemaitre's analysis showed that there is an infinity of models satisfying Einstein's equations. Similar solutions are obtained in the scalar-tensor theory. The most interesting model is the one which starts at a finite time in a state of infinite density. It was therefore inferred that, according to the theory of general relativity, the universe must be expanding, and most likely began in a state of high density. Almost immediately following this major prediction of general relativity, Hubble and Humason[7,8] conclusively established the redshift-apparent magnitude relation, which gave observational proof that the universe is expanding. Thus by 1930 Einstein's theory had made what many considered to be the greatest successful prediction in the history of science. For the next twenty years the drive in observational cosmology, almost completely in the hands of Hubble and his colleagues, was to attempt to decide from observation which of the myriad of general relativistic models best represent the universe. Soon, however, there developed an apparent paradox associated with the ages of different systems, because it appeared that the ages of various astronomical objects, notably the Earth, seemed to be greater than the age of the universe derived from the rate of expansion obtained by Hubble. Two possible paths of escape from this dilemma were the Lemaitre model with its arbitrarily long waiting period, and the steady state cosmology requiring the continual creation of matter[9,10].

The present situation with regard to this age difficulty is that we now realize that the uncertainties associated with the determination of H and those associated with obtaining the ages of the oldest stars are great enough that we no longer have any strong evidence that there is any problem. Most recently it has been stated that $H \sim 50$ km/s Mpc^{-1}, or $H^{-1} \simeq 20 \times 10^9$ years[11,12], while the age of an old galactic cluster, NGC 188, is given as 10×10^9 years[13–15], and the age of the elements obtained from the radioactive isotopes is $\sim 10 \times 10^9$ years, with uncertainties depending on assumptions made about the sequence of events leading to the isolation of U and Th in the solar system[16].

The prediction that the universe is expanding, followed by the discovery of the expansion, was the first major success of cosmology based on general relativity. The second came from the comparatively elementary discussion of the physics of the early stage in a dense expanding universe—the primaeval fireball—by Gamow and his colleagues[17,18], and the discovery in 1965, by Penzias and Wilson[19], of background radiation which may well be relict radiation from this fireball. These two predictions, followed by two major discoveries which, at first sight, appeared to confirm the theory, provide the basic scientific case for evolving models of the universe.

If we wish to account for the expansion without invoking an initially dense phase, we are left with either the steady state model in which matter is created or with an oscillating model. The steady state alternative seemed attractive to some, especially "when taken in conjunction with aesthetic objections to the creation of the universe in the remote past. For it is against the spirit of scientific enquiry to regard observable effects as arising from causes unknown (and unknowable) to science, and this in principle is what creation in the past implies"[10]. There is apparently a great gulf between those who find creation in the past acceptable, but continuous creation unacceptable, and those who have no such strong feelings. It is my belief that much of the conflict in cosmology in modern times has arisen because of this division which has little to do with science. More to the point, we must critically evaluate the detailed evidence which has accrued in the past twenty years concerning the question of whether or not we have definitely established that the universe is evolving.

Determination of q_0

In 1956 Humason, Mayall, and Sandage[20] gave a detailed account of the status of the Hubble relation. At that time the largest redshifts which had been measured were $z \simeq 0.2$. In the fifteen years that have elapsed since then, Sandage and his collaborators have worked intensively on the problem of refining the measurements of H and q_0. Many progress reports on this work have been given by Sandage[21–25]; see also Peach[26]. As far as the value of H is concerned there is some reason to believe that we are beginning to converge toward a realistic value some ten times smaller than that obtained by Hubble in 1936. As far as the determination of the deceleration parameter q_0 is concerned, the position is not so good. There are two basic reasons for this. First, very few clusters with redshifts greater than 0.2 have been discovered. The most recent plot given by Sandage[25] contains forty-two first-ranked galaxies in clusters, and only three of these, with $z = 0.29$, 0.36 and 0.46, are in excess of $z = 0.2$. The three clusters were observed by Baum[27] more than ten years ago, and a detailed discussion of his data has never been given. Many people believe that the radio astronomer's ability to detect more distant objects will lead, or has led, to an improvement of the situation. The only major achievement of radio astronomy in this connexion so far was the identification, in 1960, of 3C 295 with a galaxy with a redshift of $z = 0.46$ (ref. 28). This source lies in a cluster, and Baum obtained photometry which, combined with the redshift, gave this last point on the Hubble diagram.

About 100 galaxies associated with radio sources and 200 quasi-stellar objects, most of which are radio sources, have been optically identified, and redshifts have been obtained. None of these, with the exception of the cluster around 3C 295, has given us any information about the classical Hubble diagram beyond $z \sim 0.2$. This is because the radio sources are associated with galaxies with redshifts ≤ 0.2, or they are associated with galaxies which obviously cannot be treated as "standard candles", or they have been identified with QSOs which show a very large dispersion in the redshift-apparent magnitude diagram. Using the radio properties as a guide, we can single out a certain class of objects, but it is not clear at all that they can be used for cosmological investigations of the classical kind. If we make a table of optical types of radio galaxies as a function of increasing redshift[29], we see that, at small redshifts, almost all types of galaxy are being identified. At intermediate redshifts the galaxies are mostly giant ellipticals, while at the largest redshifts, between 0.2 and 0.3, the galaxies with published redshifts have nearly all been classified as N-type, meaning that a large part of the optical energy that they are emitting is due to non-thermal processes and hot gas rather than stars. Thus they cannot yet be used as standard candles, as the data available at present are inadequate.

Redshifts of Faint Sources

So far it has not been possible to make optical identifications and obtain redshifts of radio sources which are fainter than about 18 mag in the case of non-stellar objects (galaxies) or about 19.5 mag in the case of stellar objects. These are limits set by optical astronomy. They are set, first, by the fact that the 48 inch Palomar Sky Survey only goes down to 20.0 mag in the red and 21.1 mag in the blue; objects which are fainter than this cannot be identified unless the large reflectors, which typically have very small fields ($\sim 20'$), are used. Second, the difficulties associated with studying very faint objects are very great, because of the increasing difficulty in detecting photons against the natural and man-made noise, even with the use of image-tube techniques; also, only a very limited fraction of observing time on the large telescopes is presently devoted to this work.

Even if one admits that many of the problems can be overcome so that it will eventually be possible to measure the redshifts and do photometry of galaxies down to magnitude 21–23, we still have a problem in finding suitable objects to observe, because there is no prospect of doing surveys to this level. Sandage and his colleagues[30] are now attempting to make identifications by using very accurate radio source positions for which no optical objects can be seen at the level of the 48 inch Palomar Sky Survey. By using special photographic plates and the 200 inch telescope, they have been able to go as faint as magnitude 22 to 23 and find optical objects in some of these positions. Even when such objects are found the problem of measuring redshifts and energy distributions will be very time consuming, and it is not obvious that it will succeed. Those objects which turn out to be QSOs will be useless for this type of investigation. We can use the redshifts of those that turn out to be galaxies, but even then it will be necessary to observe other galaxies which are associated with them to obtain energy distributions which are likely to be sufficiently normal so that they can be used to derive apparent bolometric magnitudes.

Correction for Evolution

A second problem concerns the corrections to the observed energy distribution, based on the view that we are looking at standard galaxies, if they exist. These, when seen at large redshifts, are much younger than the galaxies comparatively close to us, from the viewpoint of stellar evolution. To make such corrections it is necessary to know what types of stars give rise to the bulk of the radiation from elliptical galaxies. A limited amount of work has now been done on the nuclear regions of nearby spirals and on one or two ellipticals in the Virgo cluster. This has led Sandage to conclude that the evolutionary corrections may amount to no more than 0.03 mag per 10^9 years, a value considerably smaller than earlier estimates. Tinsley has argued that theoretical models of galaxies which show a greater degree of evolution, so that the colour correction may be considerably larger, are also compatible with the observations. Most observers are doubtful of her conclusions, but it is far from clear that the present results are conclusive.

At a redshift of $z = 0.2$, the difference in bolometric magnitude of the standard galaxies, m_{bol}, to be expected between $q_0 = 0$ and $q_0 = +1$ is only 0.2 mag, while at $z \simeq 0.5$ the difference in m_{bol} between $q_0 = +1$ and $q_0 = -1$ (steady state) is 0.9 mag.

Because the three clusters with redshifts greater than 0.2 appear to lie closest to the $q_0 = +1$ relation, it has been stated for the past 10 years, with different degrees of emphasis, that $q_0 \simeq +1$. At the same time it also has sometimes been implied that q_0 is not really known at all. And, in terms of hard data, this latter statement is true. The fact that Baum's measurements have neither been published in detail nor repeated, that we have such a small amount of data anyway, and that the local anisotropy in the velocity field may affect the determination of q_0 all suggest that the numerical value of q_0 is only known to lie between wide limits; so both the exploding models and the steady state models are compatible with the measurements made so far.

Stebbins–Whitford Effect

In 1948 Stebbins and Whitford[32] published the first results of their photo-electric measurements of the colours of faint clusters of galaxies. They concluded in this preliminary investigation that after they had put in the usual corrections for the effect of the redshift there appeared to be an excess reddening which increased with increasing redshift. This meant that the distribution of energy radiated by stars in a galaxy is a function of epoch so that an evolutionary effect is present. In the early 1950s, this result was used as observational evidence against the steady state cosmology and there was some discussion in the literature about its significance[33,34]. But the result was only preliminary and by 1956 Whitford[35] no longer believed that it was correct. It was not until 1968 that Oke and Sandage[36] put this result to rest. Unfortunately, for many years after the realization by many observers that the result was spurious, theoreticians were using it as direct evidence against the steady state theory.

Counts of Radio Sources

If any class of extragalactic object is distributed uniformly in space, counts to successively increasing metric distance, and hence to fainter apparent brightnesses, will give numbers which are proportional to the volumes searched. The volumes in Riemannian space depart from the volumes calculated on the Euclidean approximation by factors which are determined by the space curvature. Hubble[37] first attempted to count optical galaxies to apply this test but he abandoned the attempt, and more recently Sandage[22] has shown that, unless we go to much fainter galaxies than can be observed from the Earth, attempts to distinguish between different cosmological models will not succeed.

The method has, however, been applied extensively to extragalactic radio sources by several groups, who have counted sources at a number of frequencies down to different minimum flux levels. The early work by Ryle and his colleagues[38,39] gave a log N–log S slope for the brighter sources of -3, far steeper than the Euclidean value of -1.5. (If N is the number of sources per steradian brighter than S, and R is the distance to a source, then $N \propto V \propto R^3$, $S \propto R^{-2}$ so that in Euclidean space $N \propto S^{-3/2}$. For distant sources in Riemannian space, $N \propto S^{-3/2} + \mu(S)$ where $\mu(S) \geq 0$ is a function depending on the maximum source distance and the cosmological model.) Quite early on it became clear that the first log N–log S slope obtained in Cambridge was far too steep, and other surveys[40–42] all led to the conclusion that at the bright end of the curve the slope is steeper than -1.5, and has a value somewhere between -1.75 and -1.85. Following Ryle and his associates it has commonly been argued that this steep slope can only be explained as being due to an excess of sources at great distances. This requires evolution of the source numbers with epoch, and is then evidence against the simple steady state theory. Observations to fainter flux levels show that the slope of the log N–log S plot gradually flattens to a slope of only ~ -0.8 at $S \simeq 0.01$ flux units (1 f.u. $= 10^{-26}$ W m^{-2} Hz^{-1}). All of these results have been obtained by making surveys at comparatively low frequencies, typical values being 408 MHz and 178 MHz. The work which has been done at higher radio frequencies (2,700 MHz) leads to a log N–log S slope of -1.4 ± 0.1 (ref. 43). If this were the only radio survey no one would have argued that significant departures from a homogenous universe exist. But it has been argued that because of the wide dispersion in spectral indices of the radio sources and their variation with flux density, the slope of the log N–log S curve should decrease with decreasing frequency of observation. The lower frequency survey containing a more homogenous source sample would then be the one most representative of the gross features of the universe. This situation naturally leads to the following unsolved problem: at what observing frequency (radio, microwave, infrared, optical, X-ray) is an unbiased sample most likely to be selected? It would really be preferable to integrate the flux over a suitably large bandwidth and then construct a log N–log S_t curve.

How can we interpret the total slope for the log N–log S curve for sources measured at low frequencies? Ryle and his associates[44,45] have argued that the data indicate that the universe must be evolving and that there was an excess of sources in an epoch defined by $z \lesssim 2$, but that at even earlier epochs the source density was much lower. The alternative proposal is that either the slope for the bright sources does not depart significantly from the Euclidean value or that its steepness is due to a statistical fluctuation in the number of very bright sources, requiring a deficit of from 5–7 sources per steradian. Hoyle[46] has argued that the remainder of the curve is directly compatible with the prediction of the steady state model. Ryle and his associates disagree with this, and argue that the whole curve can only be explained by using Friedmann models with source evolution[44,45]. The arguments depend on the details of the radio luminosity function and the exact slope of the log N–log S curve for faint sources.

Volume Effect or Luminosity Evolution?

We have optical identifications and redshifts for only a very small fraction of the extragalactic radio sources. But if we restrict ourselves to the 3C (revised) catalogue[47] containing about 250 of the brightest radio sources ($S \geq 9$ f.u.) a total of about 40 per cent of the sources including about forty quasi-stellar objects and sixty-eight galaxies have been identified and redshifts have been obtained. The identification of the QSOs seems to be complete, so the remainder of the sources are thought to be associated with galaxies for which identifications have been made but for which no redshifts have been obtained, or, in a minority of cases, for which there are no optical objects visible on the Palomar Sky Atlas at the radio positions. Plots of radio flux S against redshift have been made both for the QSOs and the galaxies[48–51] and in each case it has been found that there is no correlation between the apparent flux and the redshift. Thus it seems that for the identified sources the shapes of the log N–log S curves are attributable to a luminosity effect and not to a distance–volume effect. The key to the interpretation of the log N–log S curve for the 3C sources lies in the remaining radio galaxies. If they turn out to have systematically larger redshifts than those already measured, as has been generally assumed because they are optically fainter, then their log N–log S curve is of cosmological significance. If, however, they do not have systematically greater redshifts it must be concluded that the log N–log S curve is dominated by the effects of the radio luminosity function in a comparatively local region. The QSOs do have large redshifts. If these are of cosmological origin then their log N–log S curve and the luminosity volume test[52] do demonstrate a powerful evolutionary effect. But if the redshifts are not of cosmological origin these analyses give us no evidence of cosmological importance.

A more detailed discussion of the analyses of the counts of sources has been given elsewhere. The limitations set by the source counts on various cosmological models are summarized in Table 1 which is taken from the work of Brecher, Burbidge and Strittmatter[79]. This shows that contrary to popular opinion the counts of radio sources do not rule out a steady state universe.

Quasi-stellar Objects

The QSOs are the only extragalactic objects so far discovered which have very large redshifts.[1] Therefore they are of the greatest importance for cosmology provided that their redshifts are largely due to the expansion of the universe and do not have any other explanation. If the redshifts are of cosmological origin then the luminosity–volume test previously mentioned for the QSOs in the 3CR catalogue, or a similar analysis also carried out by Schmidt[53] for a sample of QSOs which are not powerful radio sources, leads to the conclusion that they are not distributed uniformly in space, but that the space density is very strongly dependent on z and hence on epoch. This means that they provide powerful evidence against a simple steady state universe, and if one wishes to preserve the steady state model it must be argued that it is a fluctuating steady state universe in which evolution can occur within an epoch corresponding to redshifts up to ~ 2. In any case the cut-off of redshifts beyond 2 is of great cosmological significance and some have attempted to relate this to the appropriate epoch in a universe of Lemaitre type[54,55].

None of these arguments has any validity unless it can be demonstrated conclusively that the redshifts of the QSOs are of cosmological origin, and this has simply not been achieved. There are a number of arguments that can be adduced for and against the cosmological hypothesis but there is no certain answer. Until this is reached, use of QSOs for cosmological investigation is premature.

Table 1 Limitations Set by Source Counts on Various Cosmological Models

Source	Strict steady state	Fluctuating steady state	Friedmann	Friedmann with source evolution
QSOs				
$z \rightarrow$Distance	Excluded	Allowed *	Excluded	Allowed †
$z \nleftrightarrow$Distance	Allowed	Allowed	Allowed	Allowed
Radio galaxies				
z Known $z \rightarrow$Distance	Allowed	Allowed	Allowed	Allowed
z Unknown $m_v \rightarrow$Distance	Excluded	Allowed‡	Excluded	Allowed ‡
z Unknown $m_v \nleftrightarrow$Distance	Excluded§	Allowed	Excluded§	Allowed

* Only if fluctuation to $z \sim 2$ is permitted.

† Background limits evolution to $z_{\mathrm{QSO}}^{\max}$ where $2 < z_{\mathrm{QSO}}^{\max} < 4$.

‡ Background limits evolution to $z_{\mathrm{RG}}^{\max} \lesssim 0.6$.

§ This case would require a special rather implausible luminosity function to avoid exclusion.

Microwave Background Radiation

As mentioned above, the discovery of microwave background radiation, following the prediction that primaeval fireball radiation generated in a big bang would still be present, was one of the strongest pieces of evidence for such a beginning. Is the information that we now have on the microwave background still compatible with this interpretation? Observations made at wavelengths between a few millimetres and about 20 cm fit quite well on a black-body curve with a temperature of about 2.7 K. The energy density of the radiation is then about 4×10^{-13} erg cm^{-3}. If the black-body form is confirmed, this will be the strongest evidence in favour of an evolving universe. But it is not yet certain whether or not the spectrum is really of black-body form, because the wavelength range directly observed, and not in dispute, is the Rayleigh–Jeans part of the curve where $I(\nu) \propto \nu^2$.

The observations which have been made either directly or indirectly close to and just beyond the peak of the black-body curve are in conflict unless it is argued that some very strong line radiations are present. The indirect observation of the radiation field in the galactic plane which is exciting the CN, CH and CH$^+$ interstellar molecules suggests that the temperature is less than ~ 8 K at 9.36 mm, less than 5 K at 0.56 mm, less than ~ 4 K at 1.3 mm, and it appears to be about 2.8 K at 2.64 mm. Direct observation from rockets and a balloon above the Earth's atmosphere at wavelengths in the range 0.4–1.3 mm gives a flux which corresponds to a black-body temperature of about 6 K (refs. 56–58). It is possible that the radiation detected by these observers is concentrated in a line which could be produced in a geocorona, in the Galaxy, or have a cosmological origin. The intepretation of the results is unclear at present.

If it turns out that the microwave radiation field departs strongly from the black-body form, then either extra components are present, or the radiation has a quite different origin. In both cases the answer must be that the excess radiation, or the total flux, ultimately arises in discrete sources. A number of investigations have been made in which these possibilities have been explored. The sources are most likely to be the nuclei of galaxies which radiate largely at infrared and microwave frequencies.

It was the discovery of the microwave background radiation that led to a large number of theoretical investigations concerned with the early history of the universe. What should be made clear, however, is that the existence of this radiation is very powerful evidence for an initially dense state, provided that the radiation has a black-body spectrum as is predicted in the simple theory. If it turns out that it departs strongly from the black-body shape, many attempts will undoubtedly be made to explain it in terms of a primordial radiation field plus large contributions from discrete sources, or even a more complex big bang. But this must not obscure the important point that the absence of a black-body form would mean that the prediction has not been fulfilled and the strong and direct evidence for an initial dense state will have disappeared.

This concludes my discussion of direct observational evidence bearing on whether or not the universe is evolving and began in a dense state. I believe that if one attempts to evaluate this evidence objectively there is still no really conclusive evidence in favour of such a universe.

Nucleosynthesis and Origin of Galaxies

Another approach can be taken in looking for evidence which bears on the question of whether or not the universe began in a dense state. The bulk of the mass that we see is condensed in the form of stars and galaxies with a wide range of masses and angular momenta. This matter is not distributed uniformly in space but is condensed into dense aggregates. Moreover, it has a complicated chemical composition. The major problems of cosmogony are therefore to understand the origin of the elements, and the formation of discrete objects—galaxies and other compact massive objects.

Does the existence of these features of the universe suggest that their origin is closely connected with a big bang?

I shall consider first the problem of nucleosynthesis. Early work on this problem made little progress because knowledge of nuclear physics was still comparatively primitive. It was Gamow, Alpher and Herman[59–63] who first made a serious attempt to explain the synthesis of the heavier elements from an initial dense cloud of baryons, leptons and radiation in a hot big bang. It is well known that this attempt failed due to the difficulty associated with building beyond mass 4. In the 1950s a serious attempt was made to understand the relative abundances of all of the isotopes on the assumption that they have nearly all been synthesized in the interior of stars[64]. This theory has been, in large part, highly successful and is generally accepted. It was originally thought that the fact that heavy elements are synthesized from lighter ones in stars meant that there is a slow build-up of heavy elements as a galaxy grows older, and that the relative abundance would be correlated with the ages of the stars. It is now clear that while this effect is operating, a large amount of nucleosynthesis takes place early in the life of a galaxy and the processes going on steadily throughout its life are in some ways of lesser importance.

From the point of view of cosmology the most important result is that very detailed calculations made by Wagoner, Fowler and Hoyle[65] have demonstrated conclusively that the bulk of the elements cannot have been made in a big bang. The only important element, from the point of view of nuclear physics, that could have been synthesized in a big bang is helium. Thus soon after the discovery of the microwave background radiation there was a serious attempt to argue that the helium that is detected in stars and gaseous nebulae in our own galaxy and in other galaxies is primordial helium made in a big bang. The argument appeared plausible because, on the one hand, it was suggested that the helium/hydrogen ratio is the same in different celestial objects (stars, gaseous nebulae in our own galaxy, and a few gaseous nebulae in one or two nearby galaxies) and is 25–30 per cent by mass, while, on the other hand, the fractional amount of helium relative to hydrogen that is made in a big bang is close to about 27 per cent. This simple argument broke down, however, as soon as detailed studies of different aspects of the problem were made. First of all, it was pointed out that there appear to be stars which contain very little helium so that perhaps there is no universal helium abundance. While this argument is still open, detailed studies of big bang models led to the conclusion that there are ways of making very little helium in such an initial process[66–68]. Fowler has recently emphasized that the helium–hydrogen ratio is determined completely by the choice of baryon and lepton numbers in a big bang[69], which has nothing to do with the theory of general relativity, but is tied only to initial conditions which lie outside the known laws of physics. Thus, while the helium abundance in the universe might be related to the occurrence of a big bang, there is no direct evidence that the two are related, and there are a number of alternative ways of understanding the large helium abundance found in some stars and galaxies. For example, it appears that helium could have been synthesized in massive objects evolving in the nuclear regions of galaxies.

Finally, we come to the vexed question of the origin of galaxies. As the big bang bandwagon has gained momentum, an increasing number of investigations have been carried out in which attempts are made to explain the condensation of dense objects from an initial cloud of matter and radiation which is expanding. It has been known for many years that this is very difficult to understand[70–72], and the investigations have now reached the point where it is generally accepted that the existence of dense objects cannot be understood unless very large density fluctuations in a highly turbulent medium, or otherwise, are invoked in the first place[73–75]. There is again no physical understanding of the situation; it is a condition which is put in, in a hypothetical state, to explain a major property of the universe. Thus these "theories" amount to nothing more than the statement that protogalaxies have a cosmological origin, and their origin cannot be understood any better than can the original baryons and leptons in an evolving universe. At this level therefore these theories are in no better shape than the apparently much more radical views of Ambartsumian[76,77] or Hoyle and Narlikar[78] who believe that the origin of galaxies is tied closely to the properties of the dense active nuclei and that perhaps the initial states of galaxies were high density states. Hoyle and Narlikar have even dared to suggest that perhaps "new" physics is involved. What the debate largely reduces to is that on one side there is an apparent belief by the majority that creation in the distant past is acceptable, but that creation at recent epochs is unthinkable, while on the other it is thought that there is little to choose between the two points of view, and that only with much more original work can we hope to resolve the issue. It is clear that the evolving universe concept gains no support from attempts to understand either the origin of the elements or the origin of galaxies.

Was there really a big bang? I believe that the answer clearly must be that we do not know, and that if we are ever to find an answer much more effort must be devoted to cosmological tests, with a much more openminded approach, and that much more original thinking must be done to attempt to explain the large amount of observational material, and not only that material that can be used in a narrow sense to fit preconceived ideas. Probably the best argument in favour of a beginning is the general result that the ages of many stars in our galaxy are approximately equal to H^{-1}. Probably the strongest argument against a big bang is that when we come to the universe in total and the large number of complex condensed objects in it, the theory is able to explain so little.

On the Nature of Mass

F. HOYLE & J. V. NARLIKAR
Institute of Theoretical Astronomy, University of Cambridge

The increasing number of observations of discrepant redshifts means that no longer can these be passed off as chance juxtapositions. A possible explanation of the data is given here in terms of a theory that incorporates a gravitational "constant" that is decreasing with time.

EVIDENCE concerning "discrepant redshifts" has accumulated fairly rapidly in recent months. The case where it is hardest to deny the evidence was reported at the beginning of the present year by Arp[1]. The galaxy NGC 7603 was found to be connected to an appendage by two arms which intersect at the appendage $z=0.056$. In the customary Doppler interpretation of the redshift this difference exceeds 8,000 km s^{-1}. A redshift difference of the same order was found many years ago[2] by Minkowski, Humason and Zwicky in "Zwicky's triple system". The galaxies in this system are also connected by a bridge.

If it is accepted that a discrepancy of $\sim$8,000 km s^{-1} exists for NGC 7603, then there seems no good reason for denying the two cases with discrepancies $\sim$20,000 km s^{-1} obtained by Sargent (ref. 3, and W. L. W. Sargent's contribution to the Vatican Conference, 1970). Both the latter cases are compact groups of galaxies in which one member has the discrepant redshift. Less than ten such groups have been examined. The probability of a more distant galaxy being projected against a nearer cluster by chance is small. Arp (private communication) has obtained what appears to be a jet connecting the quasi-stellar object Makarian 205, $z \simeq 0.07$, to the galaxy NGC 4319. The discrepancy is again of order 20,000 km s^{-1}.

Three cases have been observed of a quasi-stellar object apparently associated with a small compact cluster of faint galaxies. In one case Gunn has reported[4] the same redshift for the QSO as for one of the galaxies of the cluster. In the other two cases there appear to be large redshift differences (Hazard, Jauncey, Sargent and Gunn, private communication).

In a recent preprint Burbidge, Burbidge, Solomon and Strittmatter have drawn attention to a bridge which appears on the Palomar sky prints to connect the quasi-stellar object PHL 1226 to the bright galaxy IC 1746. The redshift of PGL 1226 is $z=0.404$, whereas that of the galaxy has not yet been measured, but must be small because of its brightness.

Because all objects are projected on the sky there must be some apparently peculiar juxtapositions of objects that are really at very different distances. This has hitherto led to a situation in which all but a very few astronomers have dismissed apparent redshift discrepancies as simply unusual projection effects. Yet there has to be a point of balance in one's judgment as to the extent of the chance juxtapositions one is willing to accept. One of us was aware at an early stage of the case of Zwicky's system (Zwicky, private communication) but it seemed that, in spite of the bridge, there might be a very peculiar chance juxtaposition. But the case of VV 172[3] formed the point of balance and NGC 7603 has turned the balance.

If a highly convincing theory of discrepant redshifts were available then we think there is little doubt that the data would today be considered reasonably clear-cut. It has been the absence of such a theory that has caused most astronomers to prefer to believe in unusual projection effects. If, as seems very possible, the accumulation of data forces us over a watershed (not only in our thinking but in the history of astronomy) it will clearly become necessary to arrive at a theory of discrepant redshifts. We wish to emphasize the need for a thoroughly radical assessment of the problem, considering it unlikely that a satisfactory theory will be achieved by a small change in our concepts. Explicitly, we do not think discrepant redshifts will be explained adequately either as simple Doppler peculiar motions or as excess reddening due to gravitation.

In the following discussion we shall present the usual Friedmann cosmological models and the Einstein de Sitter case in particular, from an unusual point of view. Mathematically, this point of view is at first entirely equivalent to the usual formulation. Then at a later stage we shall arrive at a possible major shift from the usual theory. The balance between the usual theory and an entirely different view both of physics and astrophysics hinges on a question raised by Dirac[5] in 1937.

It is well known that when c and $\hbar$ are set equal to unity, only a single dimensionality is needed for the whole of physics. We take this to be length and we denote the unit by L. Every quantity has a dimensional form L^n, for example, mass $\sim L^{-1}$, frequency $\sim L^{-1}$, charge $\sim L^0$, magnetic field $\sim L^{-2}$ and the gravitational 'constant' has dimensionality L^2.

Every observation is concerned with a dimensionless number, so that every observation is concerned with a product of quantities such that the dimensional dependencies on L cancel to zero. So far as experimental physics and engineering are concerned it is possible to convert a quantity of dimensionality L^n into a quantity of dimensionality L^m by means of a linear device provided $n=m$. Non-linear devices are needed if $n \neq m$. This property makes it comparatively easy to see what kind of physical device is needed to relate one quantity to another. There is no doubt that physics and engineering are made quite unnecessarily complicated by the current practice of using multiunit systems.

Because observed quantities are dimensionless they are unaffected by a scale change in the length unit. But what if we elect to change the length unit in accordance with a well behaved function $\Omega(x)$ (no zeros of Ω as well as no infinities) which varies with the position of the space-time point X? Nothing should be changed provided that first, we always combine physical quantities at the same X, and, second, every physical quantity is scaled according to its dimensionality—a quantity of dimensionality L^n being scaled by Ω^n.

Physical theories with these properties are said to be conformally invariant. This is a different kind of invariance from the coordinate invariance of relativity. Not all physical theories, however, are conformally invariant. Maxwell's theory is conformally invariant. The derivative terms of Dirac's equation are conformally invariant, but the mass term is not. Einstein's theory is not conformally invariant and physical theories cease to be conformally invariant whenever "mass" is involved. This is because the second property is then not satisfied. Clearly, we cannot expect classical dynamics to be conformally invariant unless the classical action

$$S = -\int m\,\mathrm{d}a \qquad (1)$$

of particle a is invariant. Since the element $\mathrm{d}a$ of the path of the particle becomes multiplied by Ω we would require the mass m to be multiplied by Ω^{-1}, which indeed would accord with the dimensionality of mass, $\sim L^{-1}$. But Ω can now be different at different space–time points, so that in general the mass of the particle will not be the same for all points on its path. Plainly then, we cannot expect to arrive at a conformally invariant system of dynamics so long as the mass of a particle is considered a fixed quantity belonging autonomously to the particle.

We have been concerned[6,7] since 1964 in developing a conformally invariant theory of dynamics and of gravitation. The central idea of this work is that the mass of a particle m say, is given by

$$m(X) = \lambda\, M(X) \qquad (2)$$

where λ is a coupling constant belonging to the particle itself and $M(X)$ is a "mass field" generated by all the particles in the universe. In a very general way we can write

$$M(X) = \sum_b \int P(X, B)\,\mathrm{d}b \qquad (3)$$

the summation being over all particles b, the line integral being over the world line of b, and $P(X, B)$ being a propagation function from point B at $\mathrm{d}b$ to the field point X. To avoid self-action problems in the classical theory it is convenient to add the refinement that in determining the mass of any particular particle a this particle is omitted in the summation with respect to b. A comparable situation occurs in classical electrodynamics.

Mathematically we require that when all lengths on the right hand side of (3) are changed by the function Ω the resulting mass field is multiplied by $\Omega^{-1}(X)$. This requirement is met by putting

$$P(X, B) = \lambda\, \tilde{G}(X, B) \qquad (4)$$

where $\tilde{G}(X, B)$ is the time-symmetric elementary solution of

$$\Box_x \tilde{G}(X, B) + 1/6\, R(X)\tilde{G}(X, B) = [-g(B)]^{-\frac{1}{2}}\, \delta_4(X, B) \qquad (5)$$

in which $\Box_x$ is the d'Alembertian operator, R the scalar Riemannian curvature and δ_4 the 4-dimensional Dirac delta-function. So far as we are aware the wave-equation (5) was first considered with respect to its conformal properties by Penrose.

The action of particle a is now

$$-\lambda^2 \int \mathrm{d}a \,.\, \sum_{b \neq a} \int \tilde{G}(A, B)\,\mathrm{d}b \qquad (6)$$

and the total action of all particles is given by

$$S = -\lambda^2 \sum_{a \neq b}\sum \iint \tilde{G}(A, B)\,\mathrm{d}a\,\mathrm{d}b \qquad (7)$$

Subtleties arise for a universe with infinitely many particles concerning the finiteness of (7), but the situation in this respect is not really different from the usual theory.

Enough has already been done to make the Dirac equation conformally invariant, including the mass term. To obtain conformally invariant gravitational equations we work with the usual condition that S be stationary for small changes of the metric tensor, $\delta S = 0$ for $g_{ik} \rightarrow g_{ik} + \delta g_{ik}$. The resulting equations are different and more complicated than those of Einstein. For cosmology however, and for all problems concerned with weak gravitational fields, the equations can be reduced to the Einstein form with an exceedingly high degree of approximation. The situation in regard to the classical tests of general relativity—the bending of light, the perihelion of Mercury—is therefore exactly the same as with Einstein. To effect the reduction to Einstein's equations one chooses the conformal frame so that $M(X)$ becomes independent of X. If, to begin with, $M(X)$ varies with X we simply choose $\Omega \propto M$. Particle masses are independent of X in this particular conformal frame, just as we normally take them to be.

The gravitational 'constant' comes out to be given by

$$G = \frac{3}{4\pi\, M^2} \qquad (8)$$

Again in the special conformal frame in which M is constant, G is indeed a constant. It is interesting that G is necessarily positive, so that weak gravitational fields are necessarily attractive.

It should be added that the gravitational equations do not reduce to the Einstein form in certain cases where the field is strong. The discussion of "black holes" is greatly changed, for example.

Because the gravitational theory is conformally invariant we can now effect a major simplification in discussing the isotropic homogeneous models usually employed in cosmology. These models are usually discussed with respect to the Robertson–Walker form of the line element

$$\mathrm{d}s^2 = \mathrm{d}\tau^2 - Q^2(\tau)\left[\frac{\mathrm{d}\rho^2}{1 - k\rho^2} + \rho^2\,(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2)\right] \qquad (9)$$

Here τ is cosmic time and $Q(\tau)$ is the expansion function. The coordinates ρ, θ, φ are spherical polars for an observer at the origin. The constant k can be zero or ± 1. $k = 0$ gives the Einstein de Sitter model, $k = +1$ is closed, $k = -1$ hyperbolic. It is well known that a conformal transformation function Ω can be found that changes the line element (9) into flat Minkowski space.

It is not usually possible to take advantage of this geometrical simplification because the physical theory is not conformally invariant. Here, however, the physics is conformally invariant and we can transform to Minkowski space. When we have done so the theory is as good as it was in the Robertson–Walker representation. It turns out that while the $k = 0$ case is still homogeneous in the Minkowski space

$$\mathrm{d}t^2 - \mathrm{d}r^2 - r^2\,(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2) \qquad (10)$$

the cases $k = \pm 1$ are simply localized clouds of no special interest.

The full Minkowski space, $t < 0$ as well as $t > 0$, can be used. There is, however, nothing corresponding to both halves of Minkowski space in the Robertson–Walker representation. The reason for this emerges when we make the inverse transformation from (10) to (9). The inverse transformation has a singularity at $t = 0$, and this introduces a singularity at $\tau = 0$ in (9). This singularity, which now emerges as a mathematical construct, is usually interpreted as the 'origin' of the universe. There need be no 'origin' in the Minkowski representation.

Taking the particle masses to be constant in the Robertson–Walker frame, and applying Ω^{-1} to the mass, Ω being chosen for transformation from (9) with $k = 0$ to (10), we obtain

$$m = (\text{constant}).\, t^2 \qquad (11)$$

The particle masses are a quadratic function of cosmic time t in the Minkowski representation. Even though space is now flat this leads to a redshift effect. Remembering that atomic sources emit frequencies proportional to m, we see that such a source at distance r from an observer at $r=0$ would be judged to have a redshift given by

$$1 + z = \left(\frac{t}{t - r}\right)^2 \tag{12}$$

the time of observation being t and the time of emission $t-r$.

A standard galaxy may be considered to have a specified number of stars each containing a specified number of particles arranged in the same way with respect to chemical composition. The luminosity of a star has dimensionality L^{-2}. This is proportional to m^2, and therefore by (11) proportional to the fourth power of the cosmic time. The bolometric flux from such a standard galaxy observed at time t is therefore

$$\frac{L(t-r)}{4\pi r^2} \propto \frac{(t-r)^4}{r^2} \tag{13}$$

where $L(t-r)$ is the luminosity of the galaxy at the time $t-r$ of emission of the observed radiation. Eliminating r from (13) with the aid of (12) we find that the bolometric flux depends on z according to

$$\frac{1}{1+z} \cdot \frac{1}{[\sqrt{1+z} - 1]^2} \tag{14}$$

which is the classic Hubble redshift-magnitude relation for the Einstein de Sitter model. The reader will note how much more easily we have arrived at (14) than in the usual treatment.

The present treatment is still deficient in one important respect. The form of equation (11) for the particle mass was obtained for the Minkowski representation by assuming constant mass in the Robertson–Walker representation. To make the argument complete it is essential to show that (11) follows from an explicit evaluation of (2), (3), (4), (5). This evaluation turns out to involve interesting problems which will not be considered here, since details have been given elsewhere[8]. It is convenient to choose the length unit L so that the particle density is everywhere unity. We then obtain from (2), (3), (4), (5),

$$m = \tfrac{1}{2}\lambda^2 t^2 L^{-3} \tag{15}$$

which has the required quadratic dependence on t.

Expanding (12) for $r/t \ll 1$ we obtain

$$z \simeq 2r/t \tag{16}$$

Since the Hubble constant H is defined by $z = Hr$ for small r, we have

$$t = 2H^{-1} \tag{17}$$

for the present epoch. Empirically $H^{-1} \simeq 2 \times 10^{28}$ cm. Empirically also, if we consider the particles to be hydrogen atoms, the average particle density n is given by

$$n = L^{-3} \simeq 2.5 \times 10^{-6}\ \text{cm}^{-3} \tag{18}$$

From (17), (18), and $H^{-1} = 2 \times 10^{28}$ cm,

$$nt^3 \simeq 10^{80} \tag{19}$$

This cosmological number is dimensionless, and is the number of particles contributing to the mass field $M(X)$ at the present epoch.

The dimensionless number λ^2 has no effect on gravitation, since it multiplies the action (7), and therefore disappears entirely from $\delta S = 0$, $g_{ik} \to g_{ik} + \delta g_{ik}$. But the value of λ^2 has a profound effect on the behaviour of individual particles when electromagnetic terms are added to the action. The value of λ^2 can be obtained empirically in the following way. Applying (15) to protons,

$$m_p = \tfrac{1}{2}\lambda^2 t^2 L^{-3} = 2\lambda^2 H^{-2} L^{-3} \tag{20}$$

for the present epoch. The empirical values (18) for L^{-3} and $H^{-1} \simeq 2 \times 10^{28}$ cm then lead to

$$m_p \simeq 2 \times 10^{51}\ \lambda^2\ \text{cm}^{-1} \tag{21}$$

The laboratory value of the Compton wavelength of the proton m_p^{-1} is $\sim 10^{-14}$ cm, so that empirically $m_p \simeq 10^{14}\ \text{cm}^{-1}$, and

$$\lambda^2 \simeq 5 \times 10^{-38} \tag{22}$$

is therefore required by atomicity.

The remarkable fact now emerges that

$$\lambda^2 (nt^3)^{\frac{1}{2}} = O(1) \tag{23}$$

On the left λ^2 apparently belongs autonomously to the particle, whereas $(nt^3)^{\frac{1}{2}}$ is a cosmological number. Apparently also λ^2 and n are independent of t, so that (23) would seem only a coincidence of the present epoch. This is the usual view.

At this point we reach our watershed. How if we require that (23) shall apply at all t? Then λ^2 or n, or both, must depend on t. This was the proposal of Dirac[5]. It is clear that (23) can be maintained by $n\lambda^4 \propto t^{-3}$, which allows many possible combinations of n, λ^2. Here we discuss a possibility which involves no change in the mass field $M(X)$. This possibility is similar in some respects to the case discussed by Dirac but is different in other respects. According to (2), (3), (4),

$$M(X) = \lambda \sum_b \int \tilde{G}(X, B)\, \mathrm{d}b \tag{24}$$

from which it is not hard to see that provided the product λn is independent of t there will be no change in $M(X)$. From

$$\lambda \propto n^{-1},\ n\lambda^4 \propto t^{-3} \tag{25}$$

we then get

$$\lambda \propto t^{-1},\ n \propto t \tag{26}$$

Moreover, the total action (7) is the same as before. It is as if more particles are being created by arranging that the masses of individual particles, $m = \lambda M$, shall increase linearly with t, instead of as t^2. In so far as we discuss the gravitational aspects of cosmology in terms of a smooth fluid, instead of in terms of discrete particles, nothing is changed. The interaction of each particle with the mass field M weakens as t^{-1}, but there are more particles because of $n \propto t$, and the total interaction of all particles remains the same.

An important by-product of these considerations is that the universe now becomes a perfect absorber in the sense of Wheeler and Feynman. The original Einstein de Sitter model did not meet the perfect absorber condition, which in our view is a fatal flaw of this model. The present model is not the steady state model, but by moving some way towards the steady state model, by permitting $n \propto t$, we have managed to meet an essential electrodynamic requirement.

It is possible to make a conformal transformation $\Omega \propto t$ from the Minkowski representation to a representation in which individual particle masses are constant, as we consider them to be in all terrestrial and astrophysical problems. The line

$$\mathrm{d}s^2 = \mathrm{d}T^2 - 2T[\mathrm{d}r^2 + r^2(\mathrm{d}\theta^2 + \sin^2\theta\, \mathrm{d}\varphi^2)] \tag{27}$$

which is the same as the line element of a radiation-dominated Friedmann model. The present model, however, is not radiation-dominated and it has a gravitational 'constant' that varies with time. In this representation the mass field M is proportional to $T^{\frac{1}{2}}$ and G, given by (8), is proportional to T^{-1}. Such a variation would have a profound effect on astrophysics and geophysics.

Stars would be much brighter at early T than we usually suppose them to be. There are advantages to be gained from such behaviour, but $G \propto T^{-1}$ may be too drastic[9], for example, in its effect on the past luminosity of the Sun. On the other hand, there are aspects of geophysics that seem as if they would be greatly helped by this kind of dependence. Steadily weakening gravity would gradually release the interior of the Earth from compression. It can be calculated[8] that the radius of the Earth would be required to increase at about 10 km per 10^8 yr. There is no possibility of this expansion being resisted by the crust, which must be cracked open repeatedly to make way for new surface material. At all times there would be an excess upward force on the crust at the limit of its strength. The possibility of large horizontal pressure differences, of order 10^9 dyne cm^{-2}, also exists, provided in particular regions that excess pressure is conveyed to the immediate subsurface by fluid material.

We are reminded in this connexion of the old controversy concerning continental drift. Our impression is that, while modern evidence shows unequivocally that drift actually takes place, the early calculations demonstrating the need for exceedingly large forces, really remain valid. If this is so, we would be inclined to think that some such behaviour of G as is given by our model becomes essential for an understanding of the geophysical evidence.

It may be added that Shapiro, Smith, Ash, Ingalls and Pettengill[10] have recently placed an observational upper limit of 4×10^{-10} yr^{-1} on $\dot{G}/G$. The variation expected here, with a Hubble constant of 5×10^{-11} yr^{-1}, would be 10^{-10} yr^{-1}.

We turn finally to the problem of how we should interpret $\lambda \propto t^{-1}$ in relation to the redshift problems discussed at the outset. The proportionalities $n \propto t$, $\lambda \propto t^{-1}$ maintain cosmological homogeneity. We must contemplate, however, that these proportionalities represent the smoothed-out effect of changes that could possess spatial irregularities. There could be spatially adjacent variations of λ. This we feel to be the kind of concept needed to come to grips with the problem of redshift anomalies. The smoothed-out homogeneous behaviour of the particle masses gives the normal cosmological redshift, obeying the usual Hubble relation. Local variations give anomalies. A more rapid decrease locally of λ is required in order that the anomalies be in the sense of an increased redshift. One can speculate that such variations occur as a consequence of the physical conditions in regions of strong gravitational fields. These are characterized by the condition that local particles make a contribution to the total mass field M that is comparable with the contribution of particles at cosmological distances. Such localities may be able to produce their own environmental conditions, leading to the local variations of λ.

Origin of the Alps and Western Mediterranean

K. J. HSÜ

Geological Institute, ETH, Zürich

The origin of the Alpine geosyncline may have been related to the eastward motion of Africa relative to Europe during the Mesozoic, and orogenesis in western Europe could have been caused by a westward and then a northward movement of Africa.

IN contrast to mountains such as the Himalayas and the Andes, the Alpine chain snakes its way through Europe with numerous bends, convergences and divergences[1,2]. Compared with the Atlantic, the opposite shores of which fit together almost perfectly, the Mediterranean is bounded by three peninsulas on the north, which run at right angles to the trend of the sea. To make matters worse the Mediterranean Ridge has proved to be a compressional feature[3], quite distinct from the normally extensional mid-ocean ridges.

The complex state of the Mediterranean reflects its past history and conventional interpretations have related the origin of the Alps and the Mediterranean to the interaction between the European and African plates. In many of these interpretations a broad, east-west sea (the Tethys Sea) was placed between the two continents (Fig. 1), and the Alpine folding was postulated as a consequence of the northward march of Africa[4,5]. Such a broad new picture left many of the intricacies unexplained and the important geological fact that a deep oceanic seaway did not exist in western Europe (the Alps, Apennines, and Betic Cordilleras) before the Jurassic was ignored.

Geometrical Analysis

Staub[4] considered the winding Alpine trend as a trait inherited from the European Hercynian system and thereby evaded the issue. Argand[6], however, presented a brilliant geometrical analysis and invoked continental drift and rotation of microcontinents to account for the puzzling geography of the western Mediterranean. But his kinematical analyses were based on geological data alone and have been proved untenable by recent geophysical and oceanographical discoveries. This article is an attempt to modify Argand's scheme; if the drifting chronology is revised, the geometrical displacements postulated by Argand acquire a different geological significance.

Argand[6] postulated that Africa was pushed over Eurasia in the early Tertiary, and formed the Alpine and Carpathian mountains while Eurasia was still attached to North America. After the climax of the Alpine deformation in the Oligocene,

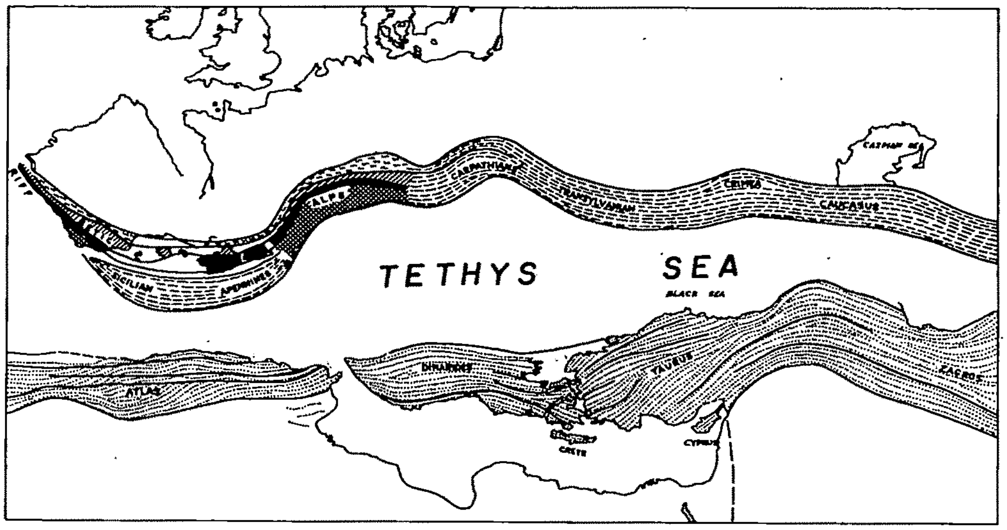

Fig. 1 A current interpretation of the Mesozoic palaeogeography of the Tethyan geosyncline (after ref. 5).

the northern margin of the African plate was bounded by the ophiolite zone of the Rif, the Betic Cordilleras, Corsica, Liguria, and the Pennine Alps in the west, and by the Carpathian Flysch in the north-east (Fig. 2). The Mediterranean was supposedly reduced into a network of epicontinental seas and Italy, Corsica, Sardinia, the Balearic Islands, and Spain were all crowded to one corner in South-Western Europe and joined to France and the stable Europe. He then postulated the start of an important phase of extension during the Late Oligocene or Early Miocene, when Africa moved south-eastward relative to Europe, inducing the rift of the Alboran Sea, causing the rotation of Spain, and creating thereby the Bay of Biscay. Meanwhile Corso-Sardinia and Italy somehow drifted counter-clockwise and left behind the Balearic and Tyrrhenian Basins. The collision of the Italian Peninsula and the Balkan block also accounted for the genesis of the Apennines.

Sphenochasm

Argand's scheme was slightly modified by Carey[5], who spoke of a Ligurian sphenochasm. The closing of such a sphenochasm should place the Corso-Sardinia Block next to the Gulf of Lyon but Carey put this block east rather than north of the Balearic Island. His reconstruction would make it almost impossible to correlate the Subbetic Zone of the Balearic Islands with the Pennine Zone of Corsica and Elba. Carey was also obliged to postulate an unwieldy set of shear motions, which could not easily be related to a rational driving mechanism. Such a scheme seems to me to be a backward step and does not represent any improvement.

But Argand's geometrical postulates do have considerable merit. The idea that the genesis of the Bay of Biscay was related to the rotation of Spain can be considered proved[7]. Several lines of evidence have supported the notion of the counter-clockwise rotations of Corso-Sardinia[8,9] and of Italy[10]. Most of Argand's chronological postulates have, however, been contradicted by new evidence; the opening of the Bay of Biscay, for example, could not have started as late as the Oligocene[11]. All the evidence indicates a Mesozoic date probably during the Late Jurassic and certainly not later than the Early Cretaceous[12,13]. There is likewise no compelling reason for assuming a Middle Tertiary rotation of Italy away from Corso-Sardinia.

The rotations postulated by Argand were supposedly caused by a displacement of the African plate south-eastwards relative to stable Europe, yet such a relative motion could not have taken place during the Late Tertiary when Europe was moving away from Greenland at such a rate that a north–south compression

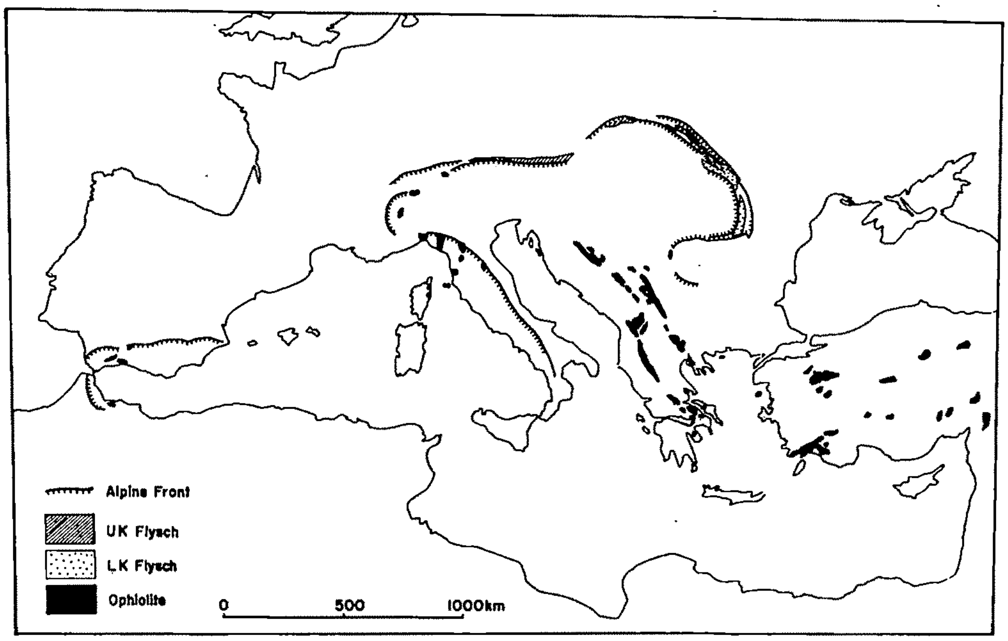

Fig. 2 Distribution of Mesozoic ophiolites and Flysch in Europe.

between Europe and Africa resulted[14]. (Pittman's important work is being completed in collaboration with Ryan, Dewey, and Bonin. Their kinematical analysis of the North Atlantic opening defined the succession of relative movements between Africa and Europe and thus paved the way for my attempt to revise Argand's chronology on the genesis of the western Mediterranean.) In fact this motion still seems to be continuing today[3].

Relative Motion

The magnetic anomaly patterns of the North Atlantic and the results of the JOIDES drilling there indicate that the history of the relative motion between Africa and Europe can be subdivided into three stages. These are (1) the Middle Jurassic to the Middle Cretaceous (165 to 80 m.y.) when the Middle Atlantic was being opened as Africa pulled away from North America[3,16]. The motion of Africa relative to Europe was eastward, because Europe was still joined to North America. (2) The Middle Cretaceous to the Late Eocene (80 to 40 m.y.) when Greenland and Europe were also being separated from North America[11]. The motion of Africa relative to Europe was then westward, as Europe was separating from North America at a greater rate[14]. (3) The Late Eocene to the Present (40 m.y. to now) when Europe was separating from Greenland. The motion of Africa relative to Europe was east and then northward.

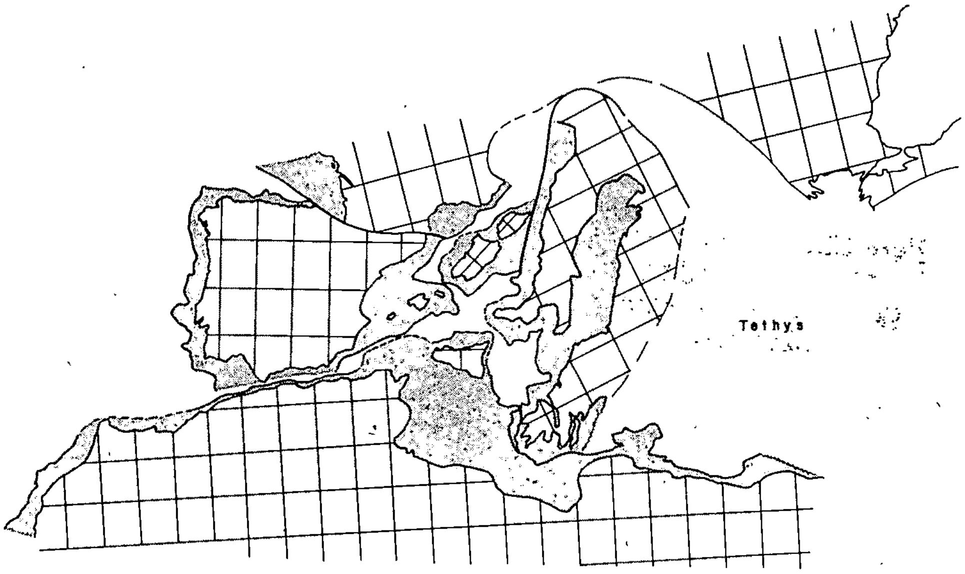

Fig. 3 Early Jurassic palaeogeography of Europe before the start of the motion of Africa eastward relative to stable Europe.

This kinematical analysis agrees well with the geological information. Stratigraphical evidence suggests unequivocally that western Europe was covered by a shelf-sea during the Triassic, when there was no oceanic seaway separating Spain from Corso-Sardinia, or Italy from stable Europe[15]. All those future microcontinents were still tucked in between Europe and Africa west of the open Tethyan Sea (Fig. 3). Thus the stage was set for Argand's postulated extensional phase in the Early Jurassic, not in the Late Oligocene[16]. Evidence of the start of crustal extension in the Jurassic is given by the first deposition of continental margin sediments in the Alps[15]. By the Middle Jurassic the oldest ophiolites of western Europe were emplaced and the microcontinents were split up, thus creating the Alpine, Apennine, Betic, and Pyrenees geosynclines (Fig. 4). The ophiolites in those deep-sea troughs were overlain by Upper Jurassic and Lower Cretaceous radiolarian and nannofossil oozes[15,17], forming the typical sequences of the Steinmann's Trinity[18].

One of the most significant drilling results of the JOIDES Legs X and XIII was the discovery of a Lower Cretaceous and Upper Jurassic pelagic sequence above an ophiolitic oceanic basement, almost identical to the coeval Alpine sequences of western Europe[3,19]. The eastward march of Africa which rotated the various microcontinents also permitted the opening of the Atlantic. The geological history of the Atlantic and the Alpine regions ran a parallel course as long as this movement continued, but the early Atlantic could not have been very broad, nor was the circulation quite normal as suggested by the abundant pyritized fossils and other Red Sea type of metallic deposits in the JOIDES cores[3,19]. Slump blocks from the nearby steep walls have also been observed[3]. But the Mesozoic Alpine geosynclines—those inland seas, a few hundred kilometres wide, which might be considered as the ancestral western Mediterranean (Fig. 4)—did not reach oceanic proportions[15].

Different Ophiolites

Alpine geologists have long recognized two different sets of ophiolites in the European Tethyan system[4] (Fig. 2). The Penninic ophiolites of the Subbetic Cordilleras, the Apennines, and the Alps could not be traced beyond the central Carpathians but a second set of Bosnian ophiolites marks the approximate position of a suture zone in the Balkans. Whereas the Penninic ophiolites are not older than Jurassic, the Bosnian ophiolites could be Triassic or even older, and Palaeozoic ophiolites from Anatolia are known[20]. These palaeozoic ophiolites were obviously the remnants of the once extensive Tethyan Sea between Eurasia and Africa. As Africa pushed the Greco-Italian Block eastward and caused it to rotate counterclockwise, the Tethyan Ocean north-east of the Block was consumed as is evidenced by the Jurassic and Lower Cretaceous Flysch of the eastern Carpathians[21,22] (Fig. 2).

The Greco-Italian microcontinent was joined onto the African plate during the Middle Cretaceous, and has moved with it ever since. (In ref. 23, D. P. McKenzie did not define precisely the present plate boundary between Africa and Europe. The possibility that Italy and western Balkan are a part of the African plate was discussed with him after the Royal Society Symposium on Plate Tectonics in February 1971. He found that my idea is not contradicted by available data on the seismicity of these regions.) Geological evidence also suggests a Late Cretaceous westward motion of the Italo-African plate;

the Austroalpine nappes of the Austrian and Swiss Alps represented the original northern margin of this Cretaceous Italo-African plate and these rigid basement blocks were thrust westward onto the Pennine ophiolites during orogenic movements which started during the Middle Cretaceous and culminated in the Late Eocene[24]. The Pennine ophiolites were almost completely consumed by the beginning of the Oligocene, at which time this northern margin of the Italo-Africa plate had a sutured contact with Europe; the debris eroded from the Austroalpine nappes were then being deposited in nearly Molasse troughs on the southern margin of the European plate.

The western margin of the Italo-African plate overrode the ophiolites of the Apennine geosyncline, giving rise to the Late Eocene deformation of the ophiolitic mélanges of Liguria and on the islands of Elba and Corsica[25-27]. The first deformation of the Betic must also have taken place during this westward motion of Africa, when the Betic ophiolitic geosyncline was almost eliminated. Unfortunately, geological evidence from this relatively poorly investigated orogenic belt is meagre.

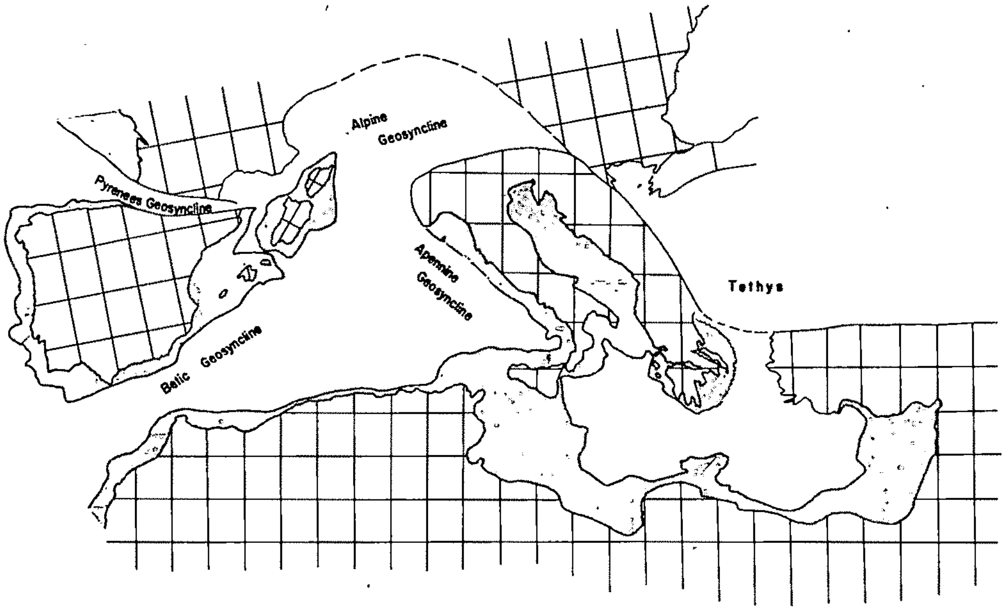

Fig. 4 Middle Cretaceous palaeogeography of Europe when the westward motion of Africa relative to stable Europe began.

Westward Movement

When the Iberian Block was joined to the African Plate during the Eocene and began to share its westward movement, the deformation of the Pyrenees commenced and may have continued during the subsequent northward movement of Africa. The present plate boundary between Europe and Africa seems to be located near the Strait of Gibraltar[23] and may represent a later development.

The kinematics of the Corso-Sardinia motion is very uncertain. Sedimentological evidence indicated that this block was still partly connected to southern France during the Early Oligocene[9], and palaeomagnetic evidence suggested a post-Oligocene rotation of Sardinia[25]. The JOIDES drilling results are also not inconsistent with a young age for the northern Balearic Basin[3]. Furthermore no Alpine ophiolite zone exists between this block and the stable Europe. Thus we tended to agree with Argand and modern Italian geologists[25] that the Corso-Sardinia block was not separated until the culmination of ophiolite deformation in the Late Eocene.

Our understanding of the origin of the Alps and the Mediterranean has been made difficult because of the last phases of the Alpine deformation which involved a northward motion of Africa relative to Europe[15]. Geological evidence of this movement is clear in the well investigated Alps, Apennines and Carpathians, but the geology is less well known elsewhere. The northward motion of Africa has continued to this day and has resulted in the underthrusting of the Hellenic Trench[3,23] and the elevation of the Mediterranean Ridge[3]. We are, however, baffled by the latest history of the Alboran Basin, where geological evidence seemed to indicate a late Caenozoic rifting[3,6] in contrast to the present state of compression[23].

We are presenting a very speculative idea in an attempt to rationalize some of the very puzzling aspects of the Mediterranean geography and geology. We are in general agreement with some of the geometrical postulates of Argand, but disagree with him on the timing of events. We postulate that the origin of the Alpine geosyncline was related to the Mesozoic eastward motion of Africa relative to Europe, and that the orogenic movements in western Europe were caused by a westward and later northward motion of Africa relative to Europe. This hypothesis is not offered as a final solution; the proposal of some definite ideas will, however, focus attention on several areas where geological and geophysical data could be synthesized and freshly gathered to check, improve, or disprove this working hypothesis.

Molecular Mechanisms of Chromosome Pairing, Folding and Function

DAVID E. COMINGS & ARTHUR D. RIGGS

Departments of Medical Genetics and Biology, City of Hope National Medical Center, Duarte, California 91010

Allosteric proteins are proposed which, on binding to specific DNA sites, undergo conformational changes that enable them to bind to each other and to control pairing, condensation, and genetic function of chromosomes.

In this article we wish to show that allosteric DNA binding regulatory proteins such as the *lac* repressor are admirably suited to direct eukaryotic chromosome folding and homologous pairing in addition to controlling gene expression. The significant properties include tight and specific binding to DNA at a unique base sequence, tight and specific interaction between their subunits, their sensitivity to inducers or effector ligands and the conformational changes induced by DNA binding. Thus these proteins would bind to specific DNA sites and undergo allosteric changes that would enable them to bind to each other or to change enzymatic activity. They could be called "nucleosteric proteins". On this basis, it is possible to propose mechanisms to account for a number of biological phenomena, such as homologous chromosome pairing, that have previously been extremely difficult to explain.

Pre-meiotic and Somatic Pairing

Chromosome pairing during meiosis in eukaryotes probably occurs in three stages[1,2]. These are pre-meiotic pairing or alignment of homologous chromosomes, chromosome synapsis mediated by the synaptonemal complex, and intimate molecular pairing between short stretches of DNA containing similar base sequences. The last stage may be initiated by the formation of heteroduplex DNA molecules[3,4] and may lead to recombination. The synaptonemal complex seems to enhance the efficiency of molecular pairing, because recombination associated with meiotic pairing is much more frequent than that associated with somatic pairing[5,6]. Yet chromosome synapsis mediated by the synaptonemal complex seems to be non-specific, for it can also pull together non-homologous chromosomes[1,2,7,8]. It seems to act by zippering together chromosomes which have their homologous telomeres attached next to each other at the nuclear membrane[1,9,10]. Thus one of the most important aspects of meiotic chromosome pairing concerns the mechanism by which homologous chromosomes become partially aligned before the formation of the synaptonemal complex[11-17]. This may be the same mechanism that is responsible for the precise somatic pairing that is seen clearly in diptera species. It must be capable of acting throughout the length of the chromosome, since complex inversions in *Drosophila* show perfect homologous somatic pairing in spite of the absence of the synaptonemal complex.

Fig. 1 illustrates a scheme by which this chromosomal pairing might be accomplished. It requires no new phenomena or forces, only the three properties already mentioned. We suggest that genes exist which code for "pairing proteins", each capable of binding specifically to a unique base sequence. On binding to DNA, these protein pairs undergo allosteric changes in surface configuration which enhance their complementarity. Their subsequent association enables homologous pairing between specific segments of the chromosomes. The allosteric modification after DNA binding prevents association of the unbound pairing proteins and ensures that the only proteins in the nucleus that can associate are those that are bound to the two homologous DNA sites. It is suggested that a series of these DNA sites and their specific pairing proteins occur throughout each chromosome. The intriguing aspect of this model is that it provides a mechanism for the pairing of native DNA molecules that is as specific and thermodynamically stable as the Watson–Crick pairing of half DNA helices.

The alternative mechanisms of homologous pairing are less appealing. For example, it could be assumed that this type of chromosome pairing is mediated by the presence of specific nucleases that keep homologous regions of DNA partially unpaired and that pairing would be mediated by heteroduplex formation between these single stranded whiskers. The difficulty with this mechanism is that it would lead to a high frequency of recombination when in fact recombination between somatically paired chromosomes is rare. Furthermore, if pre-meiotic pairing is accomplished in this manner, why should a synaptonemal complex evolve to facilitate essentially the same thing at a later stage in meiosis? A second alternative could involve the formation of a bivalent pairing protein with two identical DNA recognition sites. A fusion gene formed by unequal crossing over could produce such a protein. The bivalent pairing protein would attach first to one homologous site, then to the other. The difficulty with this scheme is that the efficiency of such a pairing protein would be reduced by competition between partially bound and unbound molecules. Furthermore, it seems unlikely that a whole series of such genes could be produced by the hazardous route of unequal crossing over.

Chromosome Folding

The proposed mechanism of chromosome pairing involves recognition sites that exist as single copies per haploid set, but it is equally plausible to propose a repetitious sequence as the recognition site, thus providing a mechanism for chromosome folding or condensation (Fig. 2). A DNA sequence repeated many times throughout the genome could recognize a specific folding protein synthesized before mitosis. This protein would be capable of self-association only after binding DNA. The net-like arrangement of chromatin that would be formed would closely resemble that seen in whole mount electron microscopy of mitotic chromosomes[18–20]. Such a mechanism could provide an explanation for the condensation of interphase chromatin when the nucleus is fused with a cell in mitosis[21]. The aggregation could be destroyed at the end of mitosis by the synthesis of new proteins that interfere with the binding of the folding protein to DNA, releasing them for destruction before the next mitosis. Shifts in cation concentration or low molecular weight ligands could also accomplish this release. Similar mechanisms could be evoked to account for the binding and release of chromatin to the nuclear membrane during the cell cycle[22–24]. The attachment of the chromosomes to localized portions of the nuclear membrane would help to ensure that they condensed on themselves rather than fusing to each other.

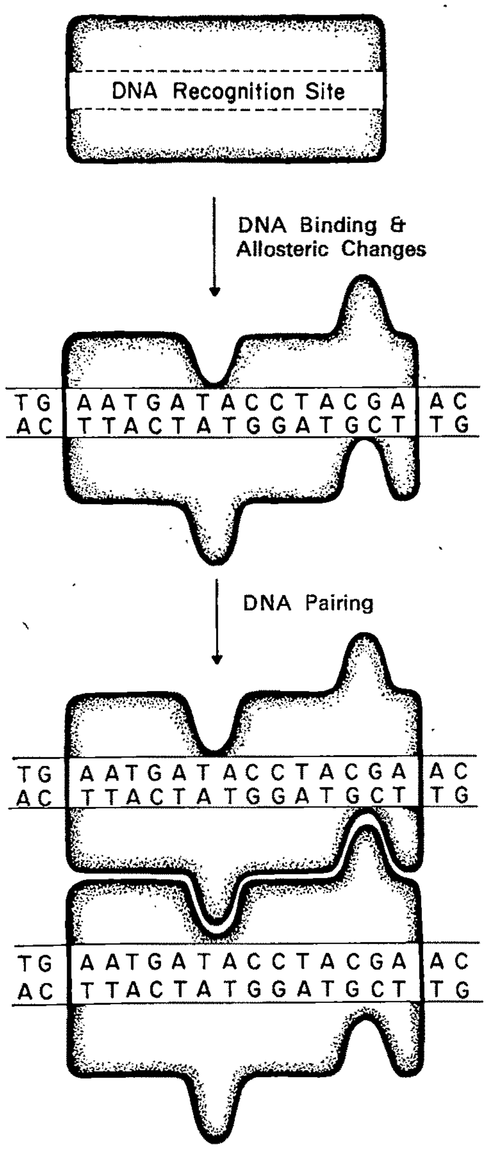

Fig. 1 A proposed mechanism of homologous chromosome pairing in somatic and premeiotic cells. Pairing proteins are synthesized which possess a DNA recognition site capable of firm binding to a specific base sequence. After binding, allosteric changes occur which allow the protein to bind itself, thus initiating the homologous pairing of that site. It is suggested that a series of such regions with their specific pairing proteins are located throughout the length of each chromosome.

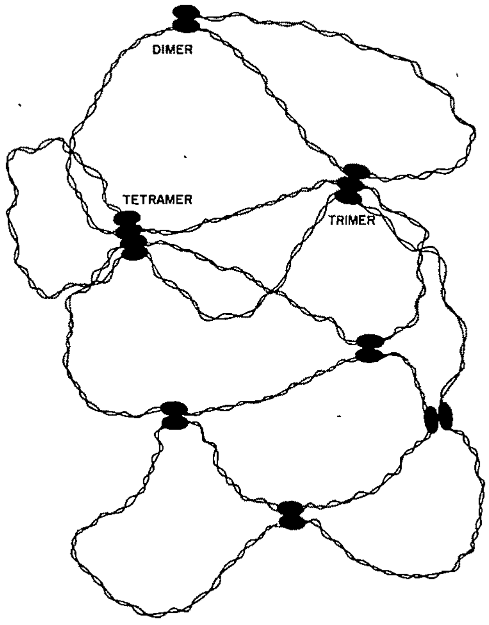

Fig. 2 Chromosome condensation or folding during mitosis could be accomplished by a repetitious DNA sequence that is recognized by a "folding protein". After binding to DNA this protein would undergo allosteric changes that allow it to bind to itself (see text).

There may be at least two categories of folding proteins, heterochromatin specific and euchromatin specific. Heterochromatin is chromatin that remains condensed and densely staining throughout interphase[25]. Many lines of evidence suggest that specific types of DNA occur within heterochromatin[26–29]. Thus, it is reasonable to propose that it may contain specific DNA recognition sites not found in euchromatin and that the folding proteins that bind to these sites are synthesized throughout the cell cycle. This could provide a simple mechanism for keeping this chromatin permanently condensed. It is also consistent with the observation that heterochromatin may be condensed less during mitosis than euchromatin[30] suggesting that its folding sites have already been taken up and that those utilized for the rest of the chromosome are different and more efficient.

Properties of Allosteric Proteins

We have proposed mechanisms that involve proteins with the properties of binding and specificity that are, as we shall show here, typical of repressor proteins. It has now been clearly shown that regulatory proteins such as the *E. coli lac* repressor can bind tightly and specifically to a unique base sequence in double stranded DNA[31–34] and similar results have been obtained for the λ and 434 phage repressor[35–37]. The *lac* repressor can identify the sequence of perhaps twenty base pairs corresponding to the *lac* operator. Twenty base pairs would be more than adequate to provide unique sequences even in genomes 1,000 times as large as *E. coli*. The *lac* repressor binds very tightly to the *lac* operator. At low salt concentrations, the dissociation constant can be less than 10^{-13} M, corresponding to a free energy change of 18 kcalories. In aqueous solution many covalent bonds are not nearly as strong. At higher salt concentrations the binding is weakened but remains very tight; in 0.2 M KCl the dissociation constant is still 10^{-11} M[32]. The binding of sequence specific proteins to DNA is certainly strong enough to hold homologous chromosomes in register, especially if there is cooperative binding at many distinct sites.

The bonding forces involved in the association of identical protein subunits to form oligomers are also sufficiently specific and strong. That the specificity and speed of association is adequate is made clear by the fact that even though there are only about ten copies of tetrameric repressor per haploid *E. coli* cell, and the concentration of subunits (which bind IPTG and would be detected) is even less[38,39] the repressor subunits assemble quickly to form active tetramers[40]. The presence of all other *E. coli* proteins does not interfere. The tightness with which repressor subunits bind to each other has not been ascertained, but since assembly takes place in such dilute solutions the bonding forces must be strong. The assembly of β-galactosidase is also rapid in dilute solution[41]. For other proteins, the binding between subunits can be as high as 13 kcalories/mol of dimer formed[42].

Allosteric proteins are by definition sensitive to effector ligands[43]. These ligands can be substrates or compounds unrelated to the substrate. Effector ligands cause or stabilize allosteric transitions which result in a changed conformation of the polypeptide chains[44,45]. Very often these conformational changes affect the subunit interaction and can promote either association or dissociation[43,44,46]. The *lac* repressor is clearly an allosteric protein in that it has a galactoside binding site distinct from the DNA binding site[33]. Furthermore, these effector ligands can change considerably the stability of repressor–operator complex. One inducing ligand, IPTG, is known to increase more than 100 times the rate of repressor–operator dissociation, while another, ONPF, stabilizes the complex[33].

There is only limited evidence at present that the conformation of the operator-bound repressor is different from that of the free repressor, but it has been shown that the apparent affinity of IPTG for DNA bound repressor is considerably less than for repressor free in solution. This strongly suggests differences in conformational state (A. D. R., unpublished data). That DNA should act as an allosteric effector, changing the conformation of the bound protein, is very plausible. Substrates often behave as allosteric effectors and when such strong binding forces are involved, it would, we feel, be more surprising if changes were not observed.

Chromosome Function

The above postulate that DNA may act as an allosteric effector leads us to suggest a novel mechanism that can account for positive control of gene activation: there may be enzymes which alter histones and which are active only when associated with their DNA binding site; these would be known, therefore, as DNA-dependent histone inactivating enzymes. The alteration of histone binding could be produced by a number of reactions including methylation, acetylation and phosphorylation[47,48]. In the micro-environment around the specific DNA binding site, the concentration of histone inactivating enzyme would be very high and the non-specific repression by histones would be greatly reduced, permitting gene expression. DNA would then serve the purpose of both activating and fixing the spatial location of regulatory enzymes.

In conclusion, we propose the existence of a class of nucleosteric proteins which bind to specific DNA sites and, on binding, undergo allosteric changes that allow them to bind to each other or to change enzymatic activity. These proteins could play a role in initiating homologous chromosome pairing, provide for the condensation of chromosomes at mitosis, condensation of heterochromatin during interphase, and they could be involved in both positive and negative control of gene function. Techniques are available to test for the existence of proteins with these unique properties.

Discrimination of Earthquakes and Explosions using Short Period Seismic Array Data

THE problem of identification of earthquakes and underground explosions on a global basis, for seismic events with body wave magnitudes (m_b) below 4.7 has not been solved[1,2], although many partially successful discriminants have been proposed. A positive identification parameter based solely on the short period seismic data is interesting as the equivalent long period energy detection threshold is often difficult to achieve, particularly at teleseismic distances.

Using data recorded at the Yellowknife short period seismic array in northern Canada, a simple two dimensional identification parameter has been found that completely separates a population of underground explosions ($4.2 \leq m_b \leq 6.2$) at the Urals, Caspian, East Kazak, Sinkiang and Novaya Zemlya test sites from a population of shallow ($h \leq 50$ km) earthquakes ($4.3 \leq m_b \leq 6.0$) within about 15° of these test sites. The data were examined in both the time and frequency domain for optimum identification parameters that could be used either singly or in a multivariant discriminant. Short period multivariant discriminants have been published in various reports of the Lincoln Laboratory of MIT[3] and have provided positive identification for events of m_b 4.7.

For the Yellowknife data, the optimum discriminant in the time domain was found to be a complexity parameter C defined as

$$C = \sum_{t=2}^{t=35} |x(t)| \qquad \sum_{t=0}^{t=2} |x(t)|$$

where $|x(t)|$ is the rectified sum of the nineteen signal channels of the array, phased to that beam that maximizes the correlogram of the P phase[4]. The algorithm, which is used to define $t=0$, is based on the correlogram and $t=0$ is assumed where the value of the correlogram first rises above a given bias value. Using this automated procedure for defining $t=0$, results in a starting time that is always fractionally later than the actual onset time of the P phase, the difference is of the order of 0.2 s. This complexity parameter is the same as one used at the Lincoln Laboratory[5] except for the definition of $t=0$.

Using the same data set, the optimum discriminant in the frequency domain was found to be the third moment of frequency (TMF), defined as

$$\mathrm{TMF} = \sum_{n=1}^{n=19} \left(\sqrt[3]{\sum_{f=0.32}^{f=5.0} (A_n(f) - B_n(f)) \cdot f^3 \Big/ \sum_{f=0.32}^{f=5.0} (A_n(f) - B(f))} \right) \Big/ 19$$

where $A_n(f)$ is the spectral amplitude at frequency f(Hz) of the first 128 samples of the signal (twenty samples per second), of the data channel n, and $B_n(f)$ is the mean spectral amplitude, at the same frequency and on the same data channel, of two noise samples taken in the 20 s before the onset of the event. If $A_n(f) < B_n(f), A_n(f) - B_n(f)$ is set to zero. The spectral amplitudes were obtained using the Cooley–Tukey algorithm, the data windows are cosine tapered by 12.5% at each end. Weichert[6], without using the $B_n(f)$ term has also found the third moment of frequency to be the optimum discriminant in the frequency domain.

The earthquake population of fifty-one shallow events was selected from the 1969 USCGS PDE lists using all those events available from the Yellowknife array digital tape library. The explosion population of twenty-seven covers the years 1968 to 1970 and likewise was obtained from all Eurasian events on the digital tape library. For some events, not all of the nineteen array channels were operational or free from system noise, but these events were still retained in the populations in order to give a realistic data sample; however, inoperative or excessively noisy array channels were omitted from the calculations of C and TMF.

Using the complexity alone results in about 20% of the explosions overlapping 40% of the earthquakes, compared with the third moment of frequency discriminant for which 20% of the explosions overlap about 15% of the earthquakes. Taking the data as a two dimensional discriminant (Fig. 1), however, a complete separation of the explosion population from the earthquake population is obtained when referenced to the arbitrary decision line $\mathrm{TMF} = 13 + 0.25 \times C$. For one

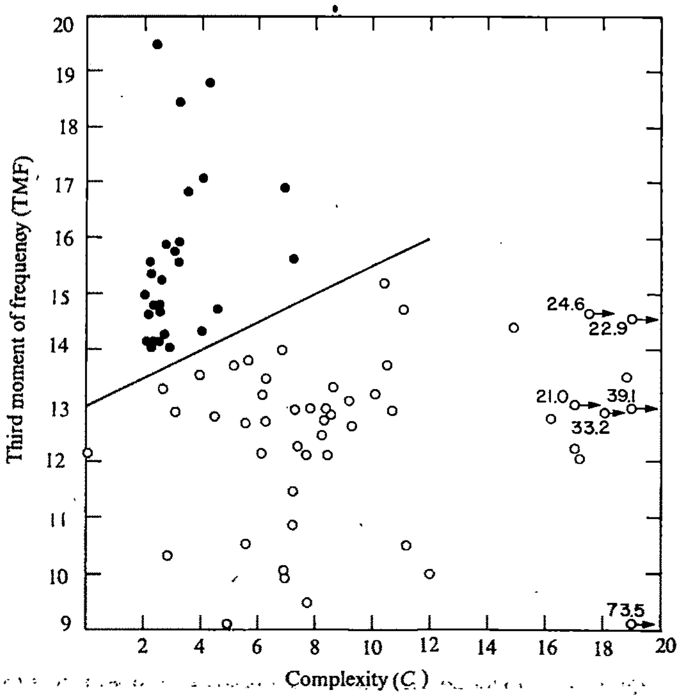

Fig. 1 Average third moment of frequency against phased beam complexity for a population of twenty-seven Eurasian explosions (●) and fifty-one shallow Eurasian earthquakes (○).

earthquake, C was set to zero as the data file was too short for the calculation of C. The orthogonal distances D of the data points from this line as a function of magnitude m_b (Fig. 2) shows D to be independent of m_b with the possible exception that the smaller explosions appear to be further from the decision line than the larger explosions. The value of D in this population has not been found to be a function of the seismic region or test area and for the earthquakes ($h < 50$ km) D has not been found to be a function of depth.

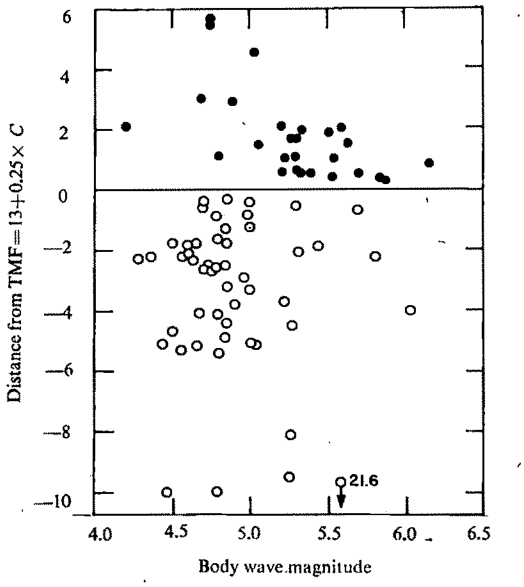

Fig. 2 Distance from the arbitrary decision line TMF=13 +0.25×C as a function of body wave magnitude for a population of twenty-seven Eurasian explosions (●) and fifty-one shallow Eurasian earthquakes (○).

The empirical conclusion is that the earthquakes, which contain the higher frequencies, are sufficiently more complex than the corresponding explosions, so that complete separation is maintained using the array data from the regions of the five test sites. Similarly the more complex explosions such as those at Novaya Zemblya maintain a sufficiently high frequency character in the first 6.4 s.

As this study has not shown any need to regionalize the data within Asia, data are being collected from other test sites and seismic areas within the third seismic zone from Yellowknife. Extensive testing will be necessary to show whether this short period discriminant will continue to hold on a worldwide basis, or for larger event populations. If it does, it will provide a positive discriminant for explosions with yields smaller than 10 kT in hard rock.

I thank P. W. Basham, K. Whitham and E. Manchee for discussions.

Black Holes as Agents of Magnetic Fields

THE recent discovery of pulsating X-ray sources[1] has led to considerable speculation that these objects might be black holes. So far no mechanisms have been seriously proposed to explain how pulsed X-rays could be produced by black holes, but it is likely that any such mechanism would require the presence of a magnetic field. I wish to point out that it is highly unlikely that the magnetic field of a black hole could ever be large enough to produce observable effects.

It is well established that sufficiently massive stars must undergo complete gravitational collapse after they have exhausted their thermonuclear energy. All available theoretical evidence[2] suggests that the final state of this collapse is a Kerr-Newman black hole. In particular, there is considerable evidence (refs. 2–5 and unpublished results of R. Price and myself) that the only electromagnetic field a black hole can have is the Kerr–Newman electromagnetic field. The Kerr–Newman electromagnetic field differs substantially from an ordinary magnetic dipole field, but its magnetic dipole moment, given by the formula[6],

$$\mu_K = |q|J/Mc$$

is a convenient indicator of the strength of the field. Here q is the charge of the black hole, J is its angular momentum, M is its mass, and c is the speed of light. One can obtain a firm upper limit on the value of μ_K from the following simple considerations: for a proton, $q_p/(\sqrt{G}\ M_p) \approx 10^{18}$ and for an electron $|q_e|/(\sqrt{G}\ M_e) \approx 10^{21}$, where G is the gravitational constant. If an uncollapsed star had a net positive charge $q > 10^{-18}\sqrt{G}\,M$ or a net negative charge $|q| > 10^{-21}\sqrt{G}\,M$, the electrostatic repulsive force on the excess protons or electrons would be greater than the gravitational attraction, and thus the excess charges would be driven away. Thus an uncollapsed star must have $|q|/(\sqrt{G}\ M) < 10^{-18}$. (On the other hand, a net positive charge somewhat less than this upper limit can be expected to occur since the less massive and faster moving electrons escape from the star more readily than protons.) No mechanism is known by which significant charge separation could occur during gravitational collapse; the above argument about the driving away of excess charge applies here also. Thus, the maximum value of $|q|/(\sqrt{G}\ M)$ that a Kerr-Newman black hole resulting from gravitational collapse could reasonably be expected to have is 10^{-18}. In fact, even if a black hole could be produced with $|q|/(\sqrt{G}\,M)$ somewhat greater than 10^{-18}, selective accretion of charged particles would be likely to lower the value of $|q|/(\sqrt{G}\,M)$ to less than 10^{-18} in a short time. In addition, for a Kerr–Newman black hole, one must have

$$\left(\frac{GM}{c^2}\right)^2 \geq \left(\frac{\sqrt{G}q}{c^2}\right)^2 + \left(\frac{J}{Mc}\right)^2$$

(This relation is necessary for the existence of an event horizon.) Thus one obtains

$$\mu_K < 10^{-18} G^{3/2} M^2/c^2$$

or, in a more readily recognizable form,

$$\mu_K < 10^{-8} (M/M_\odot)^2 \mu_E$$

where μ_E is the magnetic dipole moment of the Earth. Even this small an electromagnetic field could still have an effect on the motion of charged particles near the event horizon. But it seems highly unlikely that this magnetic field could be large enough to produce any astrophysically observable effects.

Map of the Galactic Nucleus at 10 μm

We have scanned the centre of our galaxy at a wavelength of 10 μm with a beam 5.5 arcsec in diameter. The scans have been combined to produce the map shown in Fig. 1. At 10 kpc, commonly assumed to be the distance to this region, 5.5 arcsec corresponds to 0.3 pc.

These observations were taken during the day on February 15, 1971, with the NASA 61 inch telescope at the Catalina Observatory. Because of the imprecision in the drive of the telescope, the scans could not be located accurately in declination; the telescope also drifted slowly in right ascension. These problems were overcome by comparing the scans with some made earlier by one of us (F. J. L.) and D. E. Kleinmann with the Steward Observatory 90 inch telescope. Minor distortions may persist in the map. All the features described below stand out clearly above the noise, which has a peak-to-peak value of about 6×10^{-17} W/m^2 Hz ster.

Four sources can be distinguished and are numbered in Fig. 1. An additional broad zone of emission can be seen extending to the north. Sources 2 and 4 are partially resolved and have diameters of about 0.5 pc. There are indications on the individual scans that source 2 would break up into two or three sources at higher resolution. Source 1 is unresolved and must be less than 0.2 pc in diameter. Source 3 may also be unresolved with our beam, although the ratio of signal to noise is inadequate to permit a strong statement.

We have also made observations at 2.2, 5 and 22 μm. A detailed description of all this work will be published after we have analysed it more fully. We have located the "point-like" source discovered at 2.2 μm by Becklin and Neugebauer[1] relative to our map; to within the accuracy of the measurements, its position agrees with that of Source 3. At 5 μm, scans across the complex of sources have been made at five declinations. Although these scans have a relatively low ratio of signal to noise and are insufficient in number to construct a map, they do show the same general features as the 10 μm map.

At 22 μm, we have constructed a map with the same resolution and nearly the same ratio of signal to noise as the 10 μm map. The noise for this map has a peak to peak value of about 1.8×10^{-16} W/m^2 Hz ster; at this level, sources 2 and 3 were not detected. Source 1 stands out prominently. It lies near the centre of an extended source which has a radius of about 20 arcsec.

Two field stars are plotted in Fig. 1 and labelled A and B. Additional scans at 10 μm enabled us to locate our map relative to field star A. The coordinates of this star were measured from a Palomar Sky Atlas plate, allowing us to determine the absolute position of the 10 μm sources to within about 2 arcsec. (A finding chart for the galactic centre has been published by Spinrad *et al.*[2] (their Fig. 1.) Star A is 2.5 mm south and 2.0 mm east of the indicated position of the galactic centre on this chart and star B is 1.5 mm north and 1.0 mm west. It should be noted that the position of the 10 μm sources differs somewhat from the one indicated on the published finding chart.)

From our map we estimate the total flux from the galactic centre to be $480\pm50\times10^{-26}$ W/m^2 Hz at 10 μm. The 22 μm map indicates that the flux at this wavelength is $2{,}300\pm250\times10^{-26}$ W/m^2 Hz, of which about 60% or $1{,}400\pm150\times10^{-26}$ Hz would fall within a field of view 25 arcsec in diameter. These results are in reasonably good agreement with earlier measurements made with a 25 arcsec field of view of $550\pm60\times10^{-26}$ W/m^2 Hz at 10 μm and $1{,}700\pm200\times10^{-26}$ W/m^2 Hz at 22 μm (ref. 3).

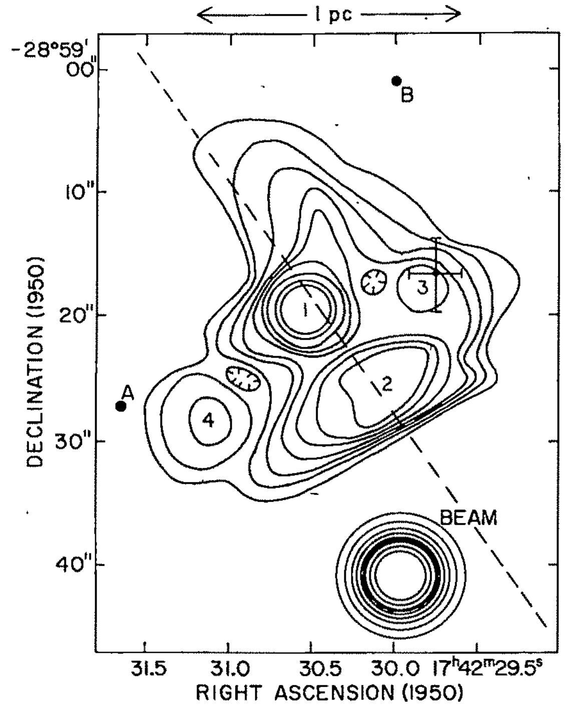

Fig. 1 Map of the galactic centre at 10 μm. The peak-to-peak noise of the observations is 6×10^{-17} W/m^2 Hz ster. The contours are at levels of 1, 2, 4, 6, 8, 10, 12, 16 and 20 times this value. The brightest 10 μm sources are numbered in order of decreasing maximum flux. The beam used for these observations has a full width at half maximum of 5.5 arcsec. It is shown with the same contour levels as are used for the map. The location of the 2.2 μm "point-like" source is indicated by a set of error bars which correspond to the uncertainty in our measurement of its position. The two most prominent field stars have been plotted and labelled A and B. The direction of the galactic plane is indicated by the dashed line.

Maps of the galactic centre at 2.2 μm have already been published[1]. At this wavelength, the detected flux arises almost entirely from unresolved stars. Except for the "point-like" source, the brightest features at 2.2 μm would produce a flux of 0.2×10^{-26} W/m^2 Hz in a field of view the size of ours. At 10 μm, the flux from these stars should be an order of magnitude lower. Our peak to peak noise is about 3.5×10^{-26} W/m^2 Hz; thus, the general stellar background detected at 2.2 μm makes virtually no contribution to the 10 μm map. Becklin and Neugebauer[4] have published the results of a scan across the galactic centre at 10 μm. Their scan seems to have passed near the centre of source 2.

The 10 μm sources fall within the region of maximum intensity of the extended 2.2 μm source, which is centred[1] at $\alpha(1950)=17$ h 42 m 30 s±1 s and $\delta(1950)=-28°\ 59'.4\pm0'.1$. Their position also agrees with that of the radio source Sgr A[5], $\alpha(1950)=17$ h 42 m 30.6 s±1 s and $\delta(1950)=-28°\ 59'\ 14''\pm15''$.

In spite of the consistency of these positions, significant ambiguities remain if one looks closely at the data. Our 22 μm map suggests that source 1 lies at the galactic centre. On the other hand, a scan across the maximum of the 2.2 μm extended source, published by Becklin and Neugebauer[4], places the greatest density of stars near source 2. The 2.2 μm "point-like" object can be identified with source 3; if it is, the 2.2 μm scan must be shifted in a direction which improves the correspondence with source 2. The existence of source 2 indicates that objects considerably cooler than normal stars lie very near the maximum 2.2 μm intensity. The contribution of these objects to the 2.2 μm flux is not known, leaving the position of the point of maximum stellar density uncertain.

Resolution of 6 arcsec at radio frequencies (D. Downes, personal communication) reveals that Sgr A consists of two objects, one to the east and one to the west of our position for the infrared sources. The published position reflects the contribution of both sources; its agreement with the infrared positions seems to be coincidental.

The first measurements of the discrete sources in the galactic nucleus were made by Low and D. E. Kleinmann[6]. These data were essential to our present efforts. We thank A. A. Hoag for giving us a plate from the Palomar Atlas and E. Roemer for assistance in carrying out the measurements.

BIOLOGICAL SCIENCES

Adaptive Significance of a Biased Sex Ratio in *Orchestia*

IN ecological studies of the marine supralittoral genus *Orchestia* (Crustacea, Amphipoda) many populations have been found that have biased sex ratios (ref. 1 and unpublished results of D. J. W.). Thelygeny has also been found in some of the terrestrial species of *Orchestia*[2], and in the sublittoral, species, *Orchestia gammarella* (Pallas), both amphogenous and thelygenous populations have been found[3]. I have investigated the possibility that biased sex ratio populations have an adaptive advantage in altering reproductive potential and the phylogenetic mechanism controlling its origin.

The annual reproductive potential (R) of an amphipod population may be expressed as:

$$R = X(bnp)$$

where X is the absolute number of adults, b the mean brood number, n the estimated number of broods in a season and p the percentage of females in the adult population. A theoretical consideration of the effect of sex ratio on R, ignoring physical and biological environmental factors and assuming b and n to be constants, is shown in Fig. 1. Unequal distribution of the sexes within a population would increase or decrease R by nearly 100%, provided each female could mate successfully. There are three categories of reproductive potential. First, there are the predominantly arrhenogenous populations in which R depends on the actual proportion of females and the intensity of male competition for mates. Second, there are those with a high or low proportion of females where mating competition is absent and the actual proportion of females controls R. And third, there are predominantly thelygenous populations where R depends on the actual proportion of males available to mate with females and possibly on the intensity of female competition for mates.

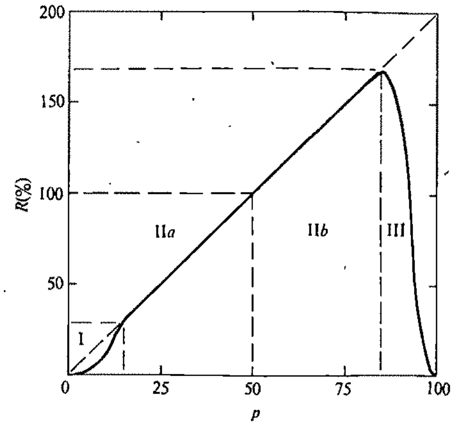

Fig. 1 Theoretical relationship between sex ratio and reproductive potential in *Orchestia*.

In *Orchestia*, a biased sex ratio may occur when the population exhibits genetically controlled monogeny, when cross fertilization is the rule, parthenogenesis is absent, males are polygamous and when only one male can inseminate a female. Although these conditions occur in many of the known species of *Orchestia*, the exact genetic control mechanisms of sex determination and monogeny remain unknown. It has been suggested that in *O. gammarella* a polygenic system is involved[4]. There are three selective mechanisms, each operated by a different physical or biological environmental condition, which may determine the degree of sex bias in a given population. These are selective mortality, unequal fertility potential of monogenous parents and selective mating. Laboratory experiments have demonstrated selective female mortality and that the reproductive potential of *O. mediterranea* A. Costa, morph *mediterranea* is reduced when substrate and food salinity is low[5]. *O. mediterranea* is a polymorphic species that, near the limit of its estuarine habitat, is replaced by morph *aestuarensis* which differs from morph *mediterranea* in dorsal pigment patterns, the incidence of intersexes and in having a high proportion of reproductive females[1]. The reproductive strategy of morph *aestuarensis* may be to maximize R (Type IIb) in the stringent estuarine conditions. It has also been shown[1] that crosses between *mediterranea* and *aestuarensis* have low fertility potential, although the reciprocal cross is fertile. In *O. gammarella*, discreet amphogenous, thelygenous or arrhenogenous colonies, apparently unrelated to physical environmental conditions, are known (ref. 3 and unpublished results of D. J. W.), although irregular fluctuations in the latter do affect optimum density conditions. In *O. gammarella* population density stresses could select biased sex ratio producing parents in isolated colonies. The mechanism would supplement the effects of density dependent regulation and provide a population homeorheostat that would maximize (Type IIb) or minimize (Type IIa) R (Fig. 2) according to the optimum permitted by the environment. An optimum R value would enable a wider range of niches to be occupied without stressing individual females. But whether natural or sexual selective processes are involved in this process is not known.

In relatively static populations which are part of a large inter-breeding group and integrated by sophisticated behavioural homeostatic mechanisms, as with many vertebrates, the stricture of Haldane[6], that natural selection cannot influence population density, applies and the increased or decreased production is wasted. The situation in *Orchestia* populations was thought to deviate from this theory, the phenomenon of sex ratio bias being limited to demes where the population is integrated by primitive social behaviour and population regula-

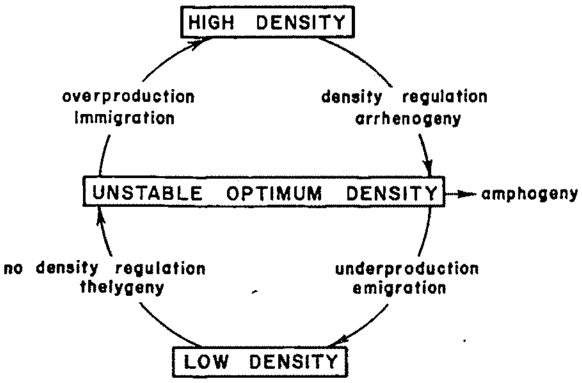

Fig. 2 Theoretical population homeorheostat in *Orchestia gammarella.*

tion methods, and/or where populations occur in discreet inbreeding colonies and are subject to irregular environmental fluctuations affecting optimum density. Sex bias would also cause a loss of genetic diversity[7] and it was expected that where environmental conditions were stable there would be a tendency for the population to maintain an unbiased sex ratio.

The gene controlling fitness to survive or breed may either be linked to the one that controls sex expression or it may be the same one. If a polymorphic supergene of this type does control sex then the possibility of group selection as an explanation of biased sex ratio is unnecessary in *Orchestia.* It has been supposed that natural selective or sexual selective forces operating at the individual level are involved in sex ratio bias and thus monogeny need have no selective value for the individual, although as has been demonstrated, it may have considerable adaptive value in regulating reproductive strategy at the population level.

I thank A. M. Gower, N. J. Poole, V. Zitko and colleagues at St Andrews for helpful discussions.

Stereoscopic Vision in the Cat

Stereopsis is the perception of relative depth by means of the disparate retinal stimulation which occurs when horizontally separated eyes are fixed on a common point. The stimulus conditions which produce stereopsis in humans have been studied thoroughly, but only recently has it been possible to study the neural mechanisms[1-4]. We have been able to demonstrate stereoscopic vision in the cat, a result which complements neurophysiological data demonstrating the presence of cells in cat visual cortex with receptive field geometry which is specialized for the detection of retinal disparity[1,2].

To test for stereopsis we used conditioned suppression[5-12], whereby an animal trained to emit a frequent response will inhibit or suppress that response on perception of a stimulus which signals a forthcoming noxious event. First, the cat was trained to lick a water-filled tube continuously for a small food reward. During these training sessions the cat viewed three real vertical rods, arrayed in the same frontal plane, each subtending 18′ and separated by 9° 33′. The rods, enclosed in a viewing tunnel, appeared as black lines seen against a back-illuminated homogeneous white projection screen, whose luminance was 0.32 foot Lamberts. Next, a conditioned suppression response was established, based on a discrimination between two real-depth positions of the centre rod. Near depth was introduced by moving the centre rod toward the cat, resulting in an angular disparity of 1° 2′ relative to the stationary side rods; 5 s later a 1 s shock was delivered through the grid floor of the restraint box and then the rod returned to its original position. Far depth was introduced by moving the centre rod away from the cat, resulting in an angular disparity of 48′, and returned to its original position 5 s later; no shock occurred during this kind of trial. Five near depth and five far depth counterbalanced trials were presented daily. Formation of the differential discrimination was clearly shown by the suppression of licking in the presence of near depth and the continuation of licking in the presence of far depth.

Once the discrimination between the near and far depth positions of the centre rod had been established, the cat was required to make the same discrimination for a rod-like shadow that appeared to move to near and far positions in stereoscopic depth. To produce this effect, a stereoscopic shadow caster was used, in which two point sources slightly separated horizontally cast the shadows of three vertical rods on a rear-projection screen. The shadows stimulated the eyes separately by means of chromatic filters (Wratten No. 58 green and No. 25A red) at the point sources and matching filters laminated to contact lenses placed in the cat's eyes. The geometric principles of shadow casting and the use of chromatic filters for dichoptic stimulation are established techniques, the theory and practical applications of which are well known[13,14]. When the point source filters and eye filters are matched left and right and the centre rod is closer to the point sources, the resulting virtual image of the centre rod appears closer to the observer than the images of the side rods (crossed disparity). When the point source filters are interchanged, the virtual images are transposed and the centre rod appears farther from the observer (uncrossed disparity).

Stereoscopic depth discrimination was tested for 7 successive days, with four near depth trials (accompanied by shock) and four far depth trials each day. The centre rod was moved a distance which produced an angular disparity of 1° 9′ (adjusted for the cat's interpupillary distance) between the centre shadow and the side shadows. Numerous blank trials, consisting of an interchange of the point source filters without movement of the centre rod, were included in the schedule; these trials produced no changes in the cat's behaviour. On all trials the eyes of the cat were observed closely, but neither eye closure nor head movement was observed.

In Fig. 1, performance on the last 3 days of real depth discrimination and on the 7 days of stereoscopic depth discrimination is expressed in terms of a suppression ratio ($W/S+W$, where W refers to the number of licks during the 5 s between rod movement and shock, and S refers to the number of licks during the 5 s preceding rod movement). There is little overlap between the distributions of near and far stereoscopic depth suppression ratios during the 7 days, a significant difference ($P<0.01$) as measured by the non-parametric matched-pairs signed-ranks test.

It is not likely that the cat based its discrimination on a cue other than stereopsis. The intrinsic nature of the shadow caster precludes most cues. Control trials eliminated the operation of a potential compound cue based on filter interchange and lateral movement of the shadows. It is logically possible that the discrimination could be made if the cat could discern which shadow stimulated each eye (that is, possessed

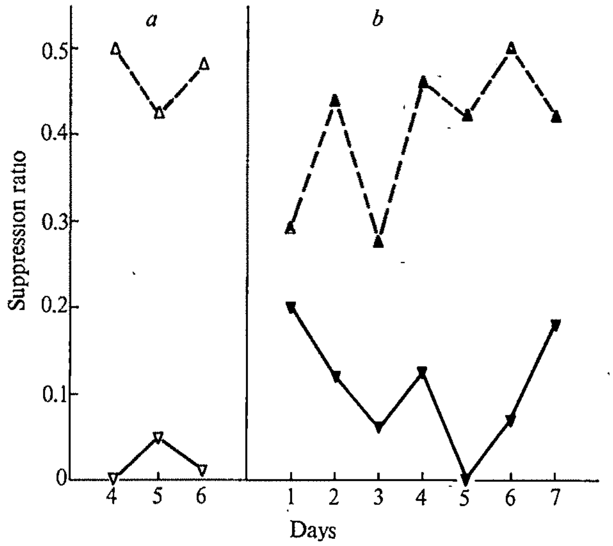

Fig. 1 Mean suppression ratios for (*a*) the last 3 days of real depth training and (*b*) 7 days of stereoscopic depth presentations. △, Backward; ▽, forward; ▲, uncrossed disparity; ▼, crossed disparity. Crossed disparity equals near stereoscopic depth; uncrossed disparity equals far stereoscopic depth. A ratio of 0.5 indicates no suppression; as ratios approach 0 suppression increases.

eye-of-origin information). Yet considerable research on humans indicates that eye-of-origin discriminations are virtually impossible[15]; humans who viewed our display could not make such discriminations. We think it unlikely that cats could readily do it when humans cannot.

Taken together, all considerations suggest that the cat possesses stereopsis and used it in making the conditioned suppression discrimination, an interpretation consistent with the neurophysiological data.

In this experiment a moving stimulus of large disparity was deliberately chosen to attract the cat's attention and, in general, to maximize the likelihood of demonstrating stereopsis. Now that the evidence suggests that the cat has some capacity for stereopsis, it should be possible to measure both the minimum and maximum limits of stereoscopic vision. Further, it may be possible to determine the ease with which cats can utilize the disparity information in random element stereograms[16,17].

We thank Drs R. Stroud, R. Althiasar and J. Greene for fitting, designing and constructing contact lenses. This study was supported in part by a US Public Health Service grant and a National Institute of Mental Health predoctoral fellowship.

Relation between Prostaglandin E_2 and Adrenaline Reversal in the Rat Uterus

THE inhibitory response of the rat uterus to adrenaline in the presence of isoprenaline inhibition can be reversed in induced oestrus but not in the progestational state, and it has been postulated that a motor substance accumulates during the isoprenaline inhibition and is released on addition of adrenaline[1]. The same sequence of events has also been observed when adrenaline was used as the initial inhibitory agent. The motor response to adrenaline is even more readily obtained in the late pregnant uterus but not in dioestrus[2].

Attempts have now been made to detect and identify the postulated motor substance. Many motor substances can be found in extracts of tissues, and to avoid confusion with these it was decided to look for the substance in the bath fluid, on the assumption that it was being released. The late pregnant uterus was chosen as a possible source because it apparently releases a greater quantity of the substance than when it is in induced oestrus, and adrenaline was used as the initial inhibitory agent. The dioestrous uterus was used to detect the substance, because reversal of adrenaline does not occur in this state. Mature female Sprague–Dawley rats weighing about 200 g were used. The stage of cycle was assessed by vaginal smearing. Pregnancies were dated and the day of finding sperm was denoted day 1. The animals were used on days 19–22. Uterine horns or strips were set up in organ baths according to a method described before[1,2]. Adrenaline (100 ng/ml.) was added to a normally contracting strip from a late pregnant uterus; immediate inhibition occurred, but after about 2 min reversal occurred and the preparation began to contract. The bath fluid was then removed and transferred to a bath containing a dioestrous horn which had been inhibited with adrenaline for the same time. Two minutes after addition of the fluid the preparation began to contract. The response was small at first, increased and then died away, after which the preparation remained inhibited (Fig. 1*a*). The bath fluid contained adrenaline, but this had no motor effect on the dioestrous uterus, and the result therefore shows that a motor substance was being released into the bath fluid from the pregnant strip.

The results of experiments with the appropriate blocking agents eliminated the possibility that the motor substance might be acetylcholine, histamine or 5-hydroxytryptamine. Among the remaining possibilities, it was decided to test for the presence of a prostaglandin. The bath fluid was removed and adjusted to *p*H 3 with N HCl and extracted twice with ethyl acetate. The extract was then evaporated to dryness on a rotary evaporator; the residue was dissolved in 1 ml. of distilled water and applied to the rat fundal strip[3]. When the active substance was present it was examined by thin-layer chromatography with the AI and AII solvent systems of Green and Samuelsson[4], using unequilibrated tanks. In ten determinations all biological activity was associated with a substance with a mean R_F of 0.66 in the AI solvent system. This behaved in a manner identical to that of a reference sample of authentic prostaglandin E_2 (R_F value 0.66), and the AII system showed it to be E_2. For confirmation parallel bioassays of the separated substance were done on guinea-pig ileum and rabbit jejunum. Prostaglandin E_2 was found in amounts varying from 30 ng to 1.5 μg in ten extracts. Prostaglandins

E_1, $F_1\alpha$ and $F_2\alpha$ were also looked for but were not found. No prostaglandin was found in bath fluids from ten control strips incubated in the absence of adrenaline. This eliminated the possibility that prostaglandin E_2 was liberated as a result of the manipulation to which the uterine tissue had been subjected.

The possibility remained that liberation of prostaglandin E_2 was purely incidental. Further experiments were therefore carried out with a reference sample of authentic prostaglandin E_2. Addition in a concentration of 20 ng/ml. to the bath fluid containing a dioestrous uterus was followed by a response which closely resembled in its course that produced by the motor substance liberated into the bath fluid (Fig. 1*b*). From this it seems that the liberation of prostaglandin E_2 was directly connected with the reversal of the inhibitory action of adrenaline.

From these results we conclude that the principal adrenergic action of the catecholamines on the rat uterus is stimulation of β-receptors resulting in inhibition. This supports the assertions of Levy and Tozzi[5]. In the presence of catecholamines prostaglandin E_2 is liberated and exerts a motor effect previously ascribed to stimulation of α-receptors in the rat uterus. Previous work has revealed anomalies in the behaviour of these receptors, and it has been suggested that they should be referred to as E-receptors pending further clarification[2]. It now seems likely that they are receptors for prostaglandin E_2. Adrenaline reversal in the rat uterus can therefore be explained by an initial β effect which is an intrinsic property of adrenaline, followed by a liberation of prostaglandin E_2 which then gives the opposite effect which has hitherto been interpreted as reversal.

Liberation of prostaglandin by catecholamines has also been observed in other organs (spleen[6], rat epididymal fat pad[7] and diaphragm[8]) and reversal of adrenaline has been documented for one of these[6]. Table 1 shows that there is a correlation between the reversal response and the effect of prostaglandin E_2 in organs other than the uterus. These responses are clearly identical, and there is therefore good reason for supposing that adrenaline reversal, wherever it occurs, is brought about by liberation of prostaglandin.

Table 1 Correlation Between the Adrenaline Reversal and Prostaglandin E_2 Responses in Various Preparations

Preparation	Adrenaline response	Adrenaline reversal response	Prostaglandin E_2 response
Rat uterus oestrogen dominated	Relaxation	Contraction	Contraction
Rat fundal strip	Relaxation	Contraction	Contraction
Gut	Relaxation	Contraction	Contraction[9]
Splenic vascular smooth muscle	Contraction[6]	Relaxation[6]	Relaxation[6]
Blood pressure	Rise	Fall[11]	Fall[10]

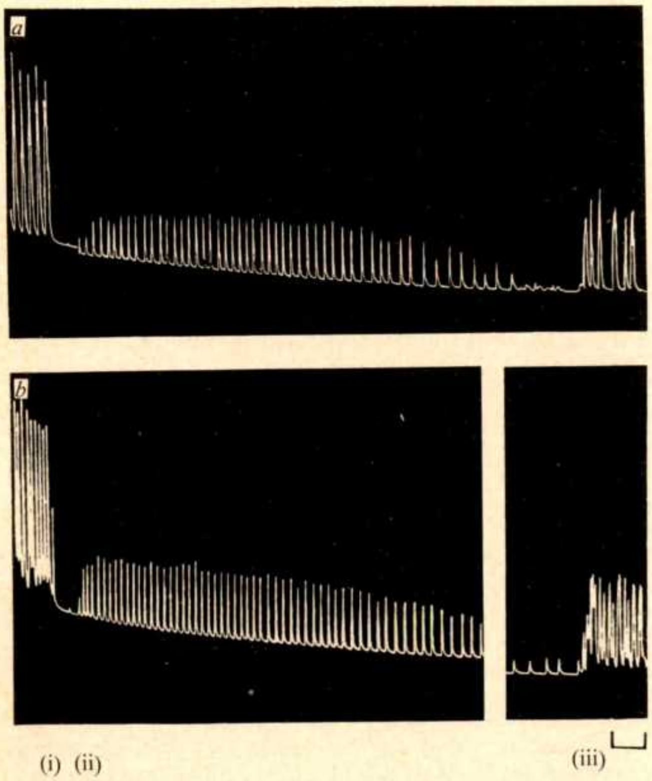

Fig. 1 Uterine horns from a rat in dioestrus. (i), Adrenaline was added to a final concentration of 0.1 μg/ml. (ii), *a*, addition of bath fluid in which a strip of uterus from a pregnant horn had been treated with the same concentration of adrenaline; *b*, prostaglandin E_2 added to a final concentration of 0.02 μg/ml. (iii) Wash. The break in *b* represents 52 min. Time marker, 5 min.

The results also indicate that the liberation of prostaglandin E_2 in the rat uterus is hormone-dependent, and this aspect of the problem and the site of liberation will be the subject of a further communication. We wish to thank Dr John Pike, of the Upjohn Co., Kalamazoo, for prostaglandin E_2.

Intrinsic Limitations in the Use of Electroantennograms to Bioassay Male Pheromones in Lepidoptera

BEHAVIOURAL assays for the male pheromone of *Trichoplusia ni* (Lepidoptera: Noctuidae) are difficult to carry out because the female apparently lacks an overt behavioural response and mating only occurs at night in very dim illumination. Grant used the electroantennogram (EAG) as an assay[1], but although this technique has developed into a useful tool to bioassay female sex pheromones in Lepidoptera, it does not seem to be a biologically meaningful approach to this receptor system.

The EAG technique is based on the fact that the high sensitivity of many male Lepidoptera to female sex pheromone is achieved by a large proportion, up to 50%, of "odour specialist" receptors which respond at high sensitivity solely to the female sex pheromone[2]. The summated response of these receptors over the length of the antenna gives the measured EAG d.c. potential change. Potential differences induced in neighbouring dendrites also summate over the length of the antenna to reinforce the effect. Only 200 pheromone molecules are needed to signal a behavioural response in males of *Bombyx mori*[3] and a single molecule is sufficient to elicit firing in one of the specialist cells.

On the other hand, the male pheromones of Noctuidae are released in large quantity, about 0.1 mg in *Leucania pallens*[4], very close to the female[5] and so to the target receptors. With so much pheromone present at the receptors, there is little relevance, in relation to natural behaviour, to behavioural or EAG measurements of threshold responses. Grant[1] shows that the excized hairpencils of one male *T. ni* cause a depolarization of 1.0 mV in both male and female antennae, whereas tufts of hair from elsewhere on the male body do not evoke a response. The EAG, however, does not show that the male can distinguish the stimulus as a pheromone from the general olfactory spectrum of the species.

I have recorded EAGs in response to male scent in a number of Noctuidae. Standard procedures were followed using KCl filled glass pipette electrodes and immobilized whole moths rather than isolated heads or antennae. EAG responses to stimuli of conspecific male brushes, to cross-specific brushes and to stimulus equivalent extracts did not differ significantly for each species regardless of whether recording from male or female antennae. Levels of EAG depolarization varied between species, but EAGs within a species were consistent in response to the stimulus of brushes from all other species used. The values obtained were: *Leucania pallens* (L.), −3.4 (±0.3) mV; *Leucania conigera* (Schiffermueller), −3.3 (±0.3) mV; *Apamea monoglypha* (Hufnagel), −2.0 (±0.2) mV; *Phlogophora meticulosa* (L.), −2.6 (±0.2) mV; and *Mamestra persicariae* (L.), −2.1 (±0.3) mV. Stimulus equivalent quantities of compounds isolated from the male brushes and various related standard laboratory compounds elicited EAGs indistinguishable from those produced by the male brushes for a range of dilutions. The isolated compounds are low molecular weight aromatics, monoterpenes and simple carboxylic acids[6]. Positive responses to such a range of compounds are not considered to be artefacts since many other related compounds do not evoke EAG responses.

Grant shows that the female sex pheromone of *T. ni* gives an EAG in the female antenna of about the same size (1 mV) as that produced in both sexes by the male brushes, whereas the female sex pheromone evokes a larger (3 mV) response in the male antenna. Grant uses Callahan's evidence of sexual dimorphism in the antennae of *Heliothis zea*[7] to suggest that perception by morphologically distinct receptors on male and female antennae explains the difference. Jefferson *et al.*[8], however, have shown that there are negligible differences in the number and distribution of sensillae between the sexes in *T. ni* There is greater variation between individuals and between antennae on the same moth. This does not support Grant's hypothesis and it seems more likely that one type of sensilla has become functionally differentiated and very narrowly specialized in the female alone.

The male releases pheromones so close to the female that there has been no selective pressure to develop a receptor which responds preferentially to minute levels of one substance. The receptors which do respond are the "odour generalists"[2], each of which has a different odour spectrum signalled, for example, by latency of rate of firing, or by speed of adaptation to a given odour. Signals from the odour generalists are deciphered by the central nervous system, and it would require an analogous detailed analysis of nerve spikes, or single cell recordings, to separate clearly the response to one odour or component thereof from that to another. EAG responses can be obtained from these receptors but, as a similar number of receptors respond to similar concentrations of many odorous compounds within the olfactory spectrum of the species, the summated EAG recordings are also similar.

EAGs show only that the male Noctuid pheromones can be perceived peripherally. For a more detailed knowledge of the way in which these chemicals stimulate or modify specific behaviour, there is no present alternative to using a behavioural assay. It is dangerous to use techniques based on response at low threshold levels by odour specialist cells to monitor processes based on neither. We still do not know what information is carried by nerve impulses, how it is integrated by the central nervous system, or even the difference between excitatory and inhibitory impulses. Where EAGs are used to investigate the behaviour of insects to olfactory stimuli, it is essential that they are closely correlated with at least laboratory behavioural studies and preferably field investigations.

I thank Drs D. Schneider and E. Priesner for very valuable discussions at Seewiesen and Drs R. T. Aplin, G. G. Grant, T. L. Payne and D. L. Wood for much helpful advice and criticism. The Anti-Locust Research Centre, London, allowed me initial use of a recording apparatus and Mr R. Yeadon gave help in its use.

Acute Effect of Oral and Subcutaneous Administration of Monosodium Glutamate on the Arcuate Nucleus of the Hypothalamus in Mice and Rats

RECENT reports by Olney that monosodium glutamate (MSG) can cause acute neuronal necrosis in the developing brain of mice[1-3], rats[1] and monkeys[4], have been the subject of intensive debate[5-11]. Some people[9,11] deny that a single subcutaneous dose of monosodium glutamate can produce any brain damage in infant rats. Although Arees and Mayer[10] confirm the existence of a necrotic lesion in both mouse and rat brain they restrict the pathology to "microglial" cells. None of these investigators attempted actually to replicate Olney's methods but used entirely different methods of preservation and staining.

Because any reports of this nature demand independent confirmation, a blind study was undertaken to determine both the presence or absence of and the consistency of an MSG effect on the developing hypothalamus of mice using the exact methods of administration of MSG, fixation and staining outlined by Olney[2] (Table 1). Further studies were completed in a similar experimental situation on Wistar rats using Olney's techniques as well as those of Adamo and Ratner[9] (Table 1).

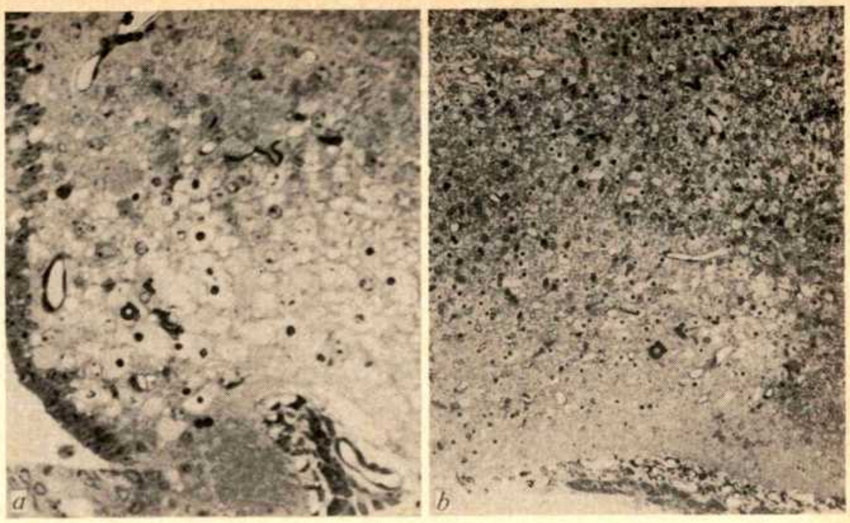

Fig. 1 *a*, Section through the hypothalamus of 10 day old Swiss albino mouse 5 h after oral administration of 1 mg/g of MSG, illustrating a distinct lesion in the region of the arcuate nuclei (AR). The neuronal elements are necrotic with a bloated cytoplasm and pyknotic nuclei (~ × 650). *b*, Section through the hypothalamus of 4 day old Wistar rat 5 h after oral administration of 4 mg/g of MSG, demonstrating a massive lesion involving the arcuate (AR) and ventromedial (VM) nuclei (~ × 450).

Monosodium glutamate was administered either orally or by subcutaneous injection. Sections for light microscopy were read independently by two of us who were unaware of the treatment schedule. Sections for electron microscopy were collected on slot grids and stained with uranyl acetate and lead citrate.

Table 1 Treatment Schedule and Fixation

Animal	Method of administration	Treatment MSG	NACl/saline	Perfusion method
Mouse	Oral	9 (1 mg/g)	9	Olney
Rat	Oral	5 (4 mg/g)	4	Olney
Rat	Oral	4 (4 mg/g)	4	Adamo and Ratner
Rat	Subcutaneous	6 (4 mg/g)	4	Adamo and Ratner
Rat	Subcutaneous	2 (4 mg/g) 2 (2 mg/g)	2	Olney

Light microscopic examination of the brains of infant mice treated orally with monosodium glutamate at a dose of 1 mg/g revealed that all the animals developed lesions in the arcuate area of the hypothalamus and median eminence (Fig. 1*a*), with complete correlation between independent examiners. No evidence of cellular pathology was noted in the controls. Light microscopic examination of the brains of infant rats treated by either route of administration with either 2 mg/g or 4 mg/g of monosodium glutamate similarly demonstrated arcuate lesions in all treated animals (Fig. 1*b*) with an absence of cellular pathology in control animals. Lesions were much more extensive in rats than mice, probably reflecting either the higher dosage used or possibly the younger age of the rats.

The infant rat brains perfused with formalin were extremely fragile. Tissue preservation was not satisfactory for photography, but the affected areas could not be identified and were in the periventricular arcuate area. The lesion could be seen better when haematoxylin and eosin were used instead of cresyl violet.

Examination of both rat and mouse material with the electron microscope revealed necrosis of the neuronal components of the arcuate nucleus. Perikaryon swelling, loss of cytoplasmic density and organelles and nuclear pyknosis are evident. The neuronal nature of these cells, at least in the mouse, is demonstrated by the presence of synaptic contacts both on cell bodies and dendrites (Fig. 2). The presynaptic components, that is, vesicles and membrane density, remain intact, while there is dissolution of the postsynaptic structure in the involved cells.

A more recent report by Olney[3] of studies using both light and electron microscopy, outlines the development of monosodium glutamate-induced lesions from acute neuronal necrosis through biological degradation and phagocytosis to an apparently normal residual cytology except for a markedly decreased population of neurones in the arcuate area. Thus, the photomicrographs of Adamo and Ratner[9], who examined only adult brains by electron microscopy and found no evidence

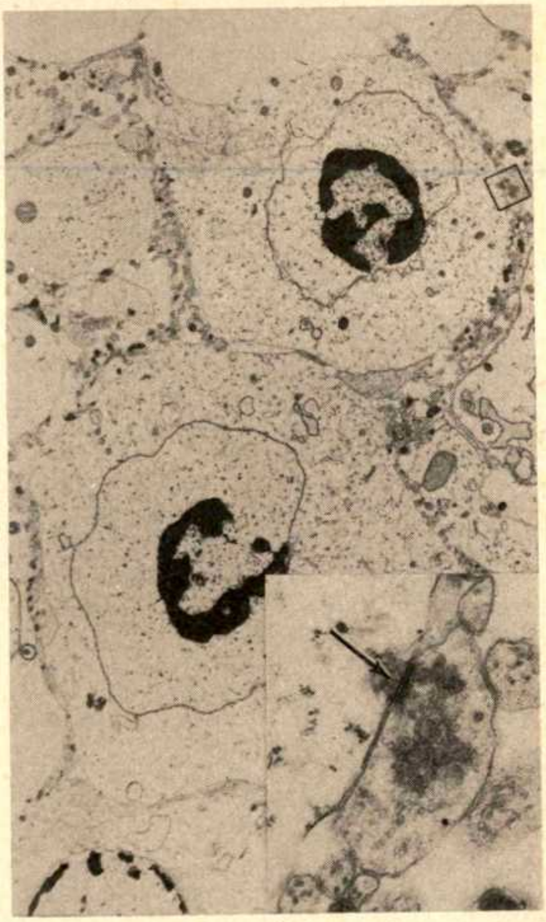

Fig. 2 Electron micrograph of degenerating neurones illustrating a dissolution of cytoplasmic components and alteration of the nuclear chromatin pattern. All the cytoplasmic structures have degenerated beyond recognition (× 12,000). The inset on the lower right is a higher magnification of the area within the box. Apparently normal axon terminal with presynaptic vesicles and increased membrane density (arrow) in synaptic contact with the soma of a degenerating cell. A remnant of postsynaptic structure is evident (× 50,000).

of cellular pathology at the ultrastructural level, are entirely consistent with Olney's[1].

The question remains why neither Adamo and Ratner[9] nor Oser *et al.*[11] found any MSG effect in their light microscopic studies of infant brains of animals. One can only speculate that the method of fixation and staining used by Adamo and Ratner obscured the existence of the lesion. On the other hand, Oser *et al.*[11] used a minimal effective dose and did not examine the rats and mice until 24 h after insult. Olney[3] has demonstrated that by 24 h after insult, all signs of oedema have disappeared and that necrotic cells are already being phagocytized. Oser *et al.*[11] reported finding occasional areas of small pyknotic neurones, large cytoplasmic vacuoles and scattered inflammatory cells. This is entirely compatible with a lesion late in evolution which would be expected if the insult was minimal.

The failure of Adamo and Ratner to find evidence of endocrine dysfunction is not surprising in face of their dose schedule. Olney[1] states that mice treated with a single dose of MSG are obese compared with control litter mates, but he does not allude to any reproductive dysfunction in this group. Reproductive dysfunction has been reported only in the group of animals treated with consecutive doses of MSG during infancy[12,13].

The interpretation by Arees and Mayer[10] that the lesion produced by MSG is limited to "microglia" but totally spares hypothalamic neurones is puzzling. Most cells normally present in the arcuate nucleus are small neurones[14]. Olney[3] has demonstrated, and we have confirmed, that most of the cells of the arcuate nucleus manifest extreme degenerative changes 5 h after MSG treatment even at the light microscopic level. The demonstration of synaptic involvement by Olney[3] and in this article, as well as the previously documented nature of the effect of MSG in the retinae[15–17], clearly points to a lesion involving neurones. These synapses were documented both on the soma and dendrites of damaged cells. Although there is considerable confusion surrounding the concept of "microglia", it is reasonably clear that axon terminals do not synapse on either the processes or the cell bodies of "microglia".

The purpose of this article is not to enter the debate on the safety of monosodium glutamate but merely to confirm or deny previous results in a scientifically valid manner. Using the exact experimental protocol described by Olney and Ho[2], and blind analysis of experimental and control specimens, we have confirmed their claim that 100% of infant mice treated orally with 1 mg/g of MSG develop hypothalamic lesions but that animals subjected to an equivalent oral dose of sodium chloride do not. The similar effect of MSG on the infant rat brain has been demonstrated by both the oral and subcutaneous route of administration. Finally, we believe that the exact duplication of experimental protocols, including age of animals, route of administration, doses and method of fixation, and careful interpretation of obtained results, in the light of carefully read previous reports, is necessary before valid comparisons can be made.

This work was supported in part by grants from the National Eye Institute. Animals were supplied by National Laboratory Animals, Missouri, and MSG was supplied by Sigma Chemical Company.

Comments on "Neuromythology"

The comments by Comfort on Dawkins's[1] memory theory struck a sympathetic chord, late though they were received here. We failed to detect any of the changes claimed[2] for the nucleus dentatus and found but a fraction[3] of the neurones estimated. Counts covering newborn to presenescent age produced no age correlation in the human olivary nucleus[4]. The need for the provision of more cell counts stressed by Comfort was emphasized too by Blinkow[5] at a recent meeting here. Neuronal population studies done by count are certainly more tedious than those based on general estimates. They render figures more like those of bankers than of economists. Delorenzo[6] found no evidence for the loss of Purkinje cells in man reported by Ellis[7]. Thus not only for rodents, but in man too, the more recent studies based on larger material, fail to demonstrate loss of neurones with advancing age. Available information about the regular Purkinje cell layer is so contradictory, the multilayered cerebral cortex with cell number estimates ranging[8,9] from 2.6×10^9 to 16.5×10^9, that it is even less likely to provide unequivocal data easily. The billion range is not of variability but one of uncertainty. Side by side illustrations demonstrating age changes suffer from what may be called the Kara Mustapha fallacy *. Recent work by Dayan[10] raises doubts about some more tenets of the neuropathology of ageing. Dawkins's model of memory helps to bring to light the narrow base supporting neurone loss as an uncontestable axiom.

Sensitivity of Fish ATPases to Polychlorinated Biphenyls

In spite of widespread concern about the possible hazards of polychlorinated biphenyls (PCBs)[1–11], little is known about the physiological action of these materials. We have therefore examined the effect of PCBs on the ATPase enzyme system, which is known to be sensitive to chemically similar compounds such as DDT[12–18].

It is known that PCB ('Aroclor 1242') will cause oedema and depress growth when fed to chicks in large amounts (200 and 400 p.p.m. in diet), the rate of steroid metabolism is increased in liver homogenates from birds dosed with PCBs and that the materials stimulate oestrogenic activity in the rat uterus[10,11]. We have examined the activity of the ATPase enzyme system in homogenized and fractionated tissues of the blue gill fish *Lepomis machrochirus*, because this system is sensitive to DDT and related compounds and because distinctive differences in effect have been found among cyclodiene-type chlorinated hydrocarbons.

Tissues were dissected, homogenized and fractionated according to the procedure reported by Koch[18]. The fraction used (B) contained mitochondria plus nerve endings. Each preparation was diluted appropriately, quick frozen in liquid nitrogen and stored at −20° C. ATPase activities were determined essentially according to the enzymatic procedure described before[19–21]. Proteins were determined by the method of Lowry *et al.*[22]. Reaction mixtures used are given in Table 1.

Table 1 Percentage Inhibiton of Mg^{2+} ATPase from Muscle of Blue Gill Fish by PCB Preparations *

Concentration (p.p.m.)	Percentage inhibition 'Aroclor 1221'	'Aroclor 1254'	'Aroclor 1268'	'Aroclor 5460'
0.03	18.7	20.6	37.2	31.9
0.33	29.9	30.6	47.1	42.9
3.33	65.4	73.1	60.3	—
10.00	80.4	84.3	67.5	—

A 3 ml. reaction mixture contained compounds at the following concentrations: 4.3 mM ATP, 5 mM Mg^{2+}, 100 mM Na^+, 20 mM K^+, 135 mM imidazole buffer (*p*H 7.5), 0.19 mM NADH, 0.5 mM PEP, 0.02% BSA, approximately 9 U pyruvate kinase and 12 U lactic dehydrogenase, and 100 µl. homogenate fraction. Absorbance changes were measured at 340 nm for 15 min using a Beckman DU spectrophotometer with temperature controlled at 27° C in reaction mixture. When used, ouabain was present at 0.85 mM. Total ATPase activity was determined in the presence of Na^+, K^+ and Mg^{2+}. Mg^{2+} ATPase activity was measured using same mixture plus ouabain. Na^+–K^+ ATPase activity is total activity minus Mg^{2+} ATPase activity[20,21]. Ethanol was used as solvent for the 'Aroclor' except 'Aroclor 1268', where acetone was used. Between 1 and 5 µl. of the 'Aroclor' solutions was added to the enzyme reaction mixture by slowly releasing the solution from a Hamilton microsyringe into a rapidly stirred reaction mixture.

* Each value represents the mean from three separate preparations. Specific activities (µmol Pi mg^{-1} protein h^{-1}; mean ±s.e.) for untreated muscle Mg^{2+} ATPase and Na^+–K^+ ATPase were 57.1±2.2 and 2.3±0.8 respectively. Low specific activity of Na^+–K^+ ATPase in muscle made accurate determinations of inhibition very difficult.

Three PCB preparations, 'Aroclor 1221', 'Aroclor 1254' and 'Aroclor 1268', and one polychlorinated terphenyl, 'Aroclor 5460' (Monsanto) were used. The last two digits of the name give the percentage chlorination of each compound, but the exact composition is not available. All compounds inhibited ATPases in low concentrations (less than 1 p.p.m.) with the most pronounced inhibition on Mg^{2+} ATPase of muscle (Tables 1 and 2). The higher sensitivity of muscle Mg^{2+} ATPase to PCB compounds is consistent with the high sensitivity of this enzyme to DDT[13–15].

'Aroclor 1254' was the most effective inhibitor of ATPases, especially Mg^{2+} ATPase, from all tissues (Tables 1 and 2). 'Aroclor 1268', an effective inhibitor of muscle Mg^{2+} ATPase (Table 1), differed from the other PCB compounds in having minimal effects on Mg^{2+} ATPase activity from other tissues (Table 2). 'Aroclor 5460' seemed to be intermediate between 'Aroclor 1268' and the other 'Aroclor' compounds in its effect on Mg^{2+} ATPase activity (Table 2). The variation between tissues, most prominent with 'Aroclor 1268', indicates that the characteristics of Mg^{2+} ATPase differ depending on tissue source. A 30–40% inhibition of Na^+–K^+ ATPase measured only on brain and kidney preparations was consistently determined for all PCBs.

Table 2 Inhibition of Mg^{2+} ATPase and Na^+–K^+ ATPase from Tissues of Blue Gill Fish

Concentration (p.p.m.)	Percentage inhibition * 'Aroclor 1221'		'Aroclor 1254'		'Aroclor 1268'		'Aroclor 5460'	
	Mg^{2+}	Na^+–K^+	Mg^{2+}	Na^+–K^+	Mg^{2+}	Na^{2+}–K^+	Mg^{2+}	Na^+–K^+
(*A*) Brain								
0.03	0.3	4.6	4.2	16.9	0.4	29.4	2.3	26.9

(*C*) Liver								
0.03	2.2		3.9		—		—	
0.33	2.6		19.4		+5.3		6.6	
3.33	2.9		24.3		+5.1		9.3	
10.00	35.8		53.0		+2.4		15.8	
16.70	45.9		74.1		6.2		—	

A, Specific activities for untreated brain, Mg^{2+} ATPase 25.2±1.0, Na^+–K^+ ATPase 35.8±2.1.

B, Specific activities for untreated kidney, Mg^{2+} ATPase 31.3±1.3; Na^+–K^+ ATPase 42.0±0.7.

C, Specific activities for untreated liver, Mg^{2+} APTase 28.5±3.0; Na^+–K^+ APTase 2.8±0.8; low specific activity of Na^+–K^+ ATPase in liver made accurate determinations of inhibition very difficult.

For reaction conditions see Table 1 except that temperature was 37° C.

* Each value represents the mean from three separate preparations.

† Plus values represent percentage activation of enzymatic activity.

In general, the PCB preparations do not reveal any obvious relationships between percentage chlorination and inhibitory effects. But the differences in action of 'Aroclor 1268' on Mg^{2+} ATPase from different tissues and the similarities in effects between PCBs and DDT require further study.

Effect of Pregnancy on the Isoantibody Response in Rabbits

WHEN an Rh-negative woman becomes pregnant for the first time with an Rh-positive foetus, the immune response to Rh-positive foetal red cells entering the maternal circulation is usually manifested by the appearance of antibodies after delivery or by priming without detectable antibodies, which only appear during a subsequent Rh-positive pregnancy[1]. The appearance of antibodies during the first pregnancy, in the absence of any known prior stimulus with Rh-positive blood, is not as rare as was formerly thought. A minimum of 1% of such women can be found to have antibodies at the end of the first preganancy, and they appear during the later months of ABO-compatible pregnancies[2].

Although the passage of foetal cells into the maternal circulation is most frequent and intense as the result of labour, it also occurs during pregnancy particularly during the third trimester[2]. The relative infrequency of antibodies at the end of the first pregnancy and the frequent delay in their first appearance after delivery has led to the suggestion that women possess a diminished immune responsiveness to foetal red cell antigens during pregnancy[3,4], but the only direct experimental evidence is that of Merritt and Galton[5], who found that the antibody response of three different species of experimental animal to sheep red blood cells, bacterial endotoxin and bovine γ-globulin respectively, was the same in pregnant as in non-pregnant animals.

To obtain further information on this point, but using an iso-antigenic system, random-bred Californian virgin female Hg^{A}-negative rabbits were mated and injected intravenously with 2×10^{9} Hg^{AF} red cells at varying intervals after mating. One blood donor was used throughout the experiment. In an initial group of rabbits (group 1) the injections were given 14 days after mating, and in those that became pregnant the interval between the stimulus and delivery of the litters was found to be 17–20 days. A second group of rabbits (group 2) was injected at approximately 21 days after mating, the interval between stimulus and delivery being 9–13 days. Samples of venous blood were obtained from each rabbit at the beginning of the experiment and at 10, 20 and 30 days after the injection of red cells. The sera were tested for haemagglutinating anti-Hg^{A} antibodies using papainized Hg^{A}-positive red cells.

Table 1 Anti-Hg^{A} Response in Rabbits Injected 14 days after Mating

	Pregnant rabbits 20 days after stimulus	Pregnant rabbits 30 days after stimulus	Non-pregnant rabbits 20 days after stimulus	Non-pregnant rabbits 30 days after stimulus
Anti-Hg^{A} present	10 (55.6%)	10 (55.6%)	7 (41.2%)	9 (53.0%)
Anti-Hg^{A} absent	8	8	10	8
Totals	18	18	17	17

Tables 1 and 2 give the results of testing for antibodies in the two groups of rabbits, which are divided into those that became pregnant as a result of the mating and those that did not, the latter acting as controls. (The overall incidences of anti-Hg^{A} in the control rabbits was 51% which is very close to the 56% incidence found in a group of non-mated control animals in a previous study[6].) The incidence of positive tests for antibodies is given both for tests taken at the time when the pregnant rabbits reached the end of gestation and for tests taken 30 days after the stimulus. The latter are included because the pregnant state might have influenced not only the development of antibodies up to the point of delivery, but also their appearance in the post-gestational period. Previous experience[6] had shown that if antibodies were to develop they had done so by 30 days after the stimulus.

Table 2 Anti-Hg^{A} Response in Rabbits Injected 21 Days after Mating

	Pregnant rabbits 10 days after stimulus	Pregnant rabbits 30 days after stimulus	Non-pregnant rabbits 10 days after stimulus	Non-pregnant rabbits 30 days after stimulus
Anti-Hg^{A} present	7 (50%)	12 (85.7%)	11 (32.4%)	17 (50%)
Anti-Hg^{A} absent	7	2	23	17
Totals	14	14	34	34

In group 1, samples taken 20 days after the stimulus, that is, at a time when pregnant rabbits reached the end of gestation, showed that 41.2% of non-pregnant rabbits had antibodies, while these were detected in 55.6% of pregnant animals. The difference is not significant. During the subsequent 10 days, two further non-pregnant rabbits developed antibodies, the final incidences in the two groups becoming almost identical. In group 2, tests or samples taken 10 days after the stimulus, that is, at a time when the pregnant rabbits were at the end of their gestation period, showed that 32.4% of non-pregnant rabbits had antibodies, compared with 50% of pregnant animals. During the subsequent 20 days a further eleven developed antibodies, the final incidences being 50% for non-pregnant and 85.7% for pregnant animals.

There is thus no evidence that during pregnancy the rabbits showed any diminished unresponsiveness to Hg^{A}-positive red cells. The peak titres of antibody reached in responding rabbits varied from 1 : 1 to 1 : 256, and there was no difference in the distribution of titres between pregnant and non-pregnant rabbits. There is a suggestion of an increased responsiveness in group 2 pregnant rabbits, but the difference from controls is not significant. The litters included both Hg^A-positive and Hg^A-negative rabbits, and although it was not possible to blood group all the newborn animals, analysis of those that were grouped showed that whether or not the mother developed antibodies was unrelated to the blood groups of the litter. Spontaneous immunization of Hg^A-negative rabbits by their Hg^A-positive foetuses has not been demonstrated[7], and in the present experiment, animals carrying Hg^A-positive foetuses appeared no more tolerant of the injected Hg^A-positive red cells than did those carrying only Hg^A-negative foetuses.

Evidence for a depressed immune response during pregnancy comes largely from experimental allograft studies. It has been found that depression of allograft rejection during pregnancy may be (*a*) non-specific, that is, random grafts are better tolerated by pregnant than non-pregnant animals[8-10], or (*b*) specific in that allografts possessing paternal antigens are better tolerated than other allografts[9,10].

It has been suggested[10,11] that specific unresponsiveness may be related to the development in the mother of enhancing antibodies, and Currie was able to transfer such unresponsiveness to a paternal strain tumour with serum from interstrain pregnant mice. The ability to develop certain types of antibodies to paternal antigens may thus be an important event in pregnancy. Anti-leucocyte antibodies occur frequently in human pregnancy and are not uncommon even in a first pregnancy[12]. This study shows that iso-antigens on red cells of the rabbit are capable of producing a normal antibody response in pregnant females.

We thank Professor Carl Cohen for typing rabbits and supplying antisera.

Brain Catecholamines and Human Sleep

We have previously noted what seemed to be marked discrepancies between human and other mammalian species in the association of serotonin and sleep[1-3]. Furthermore, L-dopa, the immediate precursor of dopamine and noradrenaline, by producing a decrease in human rapid eye movement (REM) sleep[4] (an opposite effect from the predictions based on animal studies[5]), indicated that there might also be differences between human and other mammalian species in the adrenergic system. To further determine the role of the adrenergic nervous system in human sleep we studied the effect of depleting brain catecholamines by administration of alpha-methyl-*d* l-paratyrosine (AMPT) and alpha-methyl-*P*-phenylalanine (AMPHe), which are potent and specific inhibitors of catecholamine synthesis[6,7].

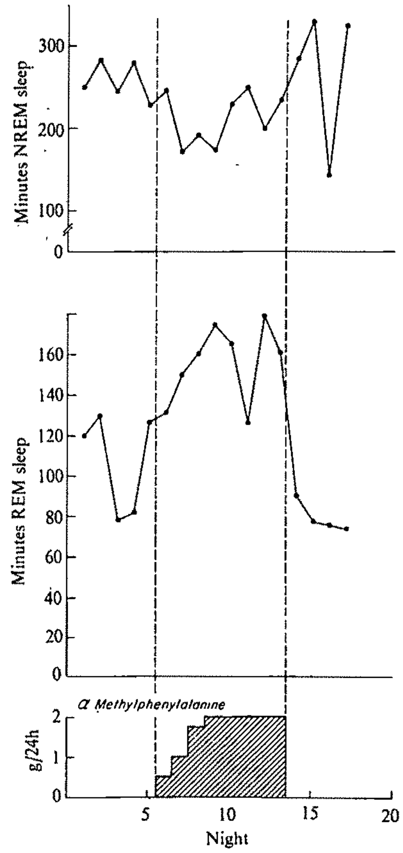

Fig. 1 Changes in rapid eye movement (REM) and non-rapid eye movement sleep (NREM) in patient (S. M., 42♀) taking alphamethylphenylalanine.

Five men and three women (two with essential hypertension, four with pheochromocytoma, one with Huntington's chorea and one with dystonia musculorum deformans) were studied by continuous all-night recording of electroencephalogram, electroculogram and electromyogram. Drugs were administered for therapeutic purposes. Each patient slept in his regular hospital room and, except for J. P. and B. F., who were allowed to sleep as late in the morning as they wished, was left undisturbed until awakened after 8 h of possible sleep. Previous medications were discontinued for at least 10 days before the beginning of the study. A constant number of identical capsules containing either placebo or active drug were administered four times each day with a maximum dose of 2–3 g per 24 h period. The protocol consisted of consecutive periods of pre-drug baseline placebo and active drug and post-drug placebo. Patients received no other drugs, and daytime naps were prohibited. Records were evaluated by standard criteria[8] by a scorer unaware of the patient's drug status. The first 2 nights were used to adapt the patients to the slightly unnatural sleeping conditions and were not included in the results. Sleep records during the first 5 nights after the daily drug dose exceeded 0.75 g were analysed. During pre-drug and post-drug placebo periods, data from 3–14 successive nights were examined.

In all eight patients, AMPT or AMPHe administration was associated with an elevation in total REM sleep (Table 1), ranging from 3–52%. This increase seemed to be related to an increase in the length of each REM period, because the total number of REM cycles was not affected. Three patients on AMPT had decreases in REM sleep after five nights, although the two other patients maintained the REM increase for the full period of drug administration (eight nights) as did the patients on AMPHe (Fig. 1). There was no change in non-rapid eye movement (NREM) sleep. When AMPT was discontinued there was a decrease in both types of sleep. The NREM decrease (20–80%) from pre-AMPT baseline was seen in three patients for only 1–2 nights and is not reflected in the post-AMPT NREM sleep mean (Table 1). There was a REM sleep post-AMPT decrease (3–77%) in the five patients which persisted for up to six nights. In one patient (Fig. 1), studied after discontinuation of AMPHe there was a 25% decrease in REM sleep accompanied by a 27% increase in NREM sleep. A Friedman's analysis of variance of the overall REM means for the three was significant ($P<0.05$). There were no significant changes for NREM sleep. All patients reported increased daytime sleepiness on AMPT but not on AMPHe.

* Mean for number of nights given in parentheses. (+) $P<0.05$ for difference from pre-AMPT treatment concentrations. (++) $P<0.02$ for difference from AMPT treatment concentrations. (+++) $P<0.05$ for difference from pre-AMPT treatment concentrations.

As a test of the effect of AMPT on cerebral monoamine metabolism, cerebrospinal fluid concentrations of homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5-HIAA) were determined in two patients from whom sleep studies were available and in three further subjects who were receiving similar dosages of AMPT (Table 1). Lumbar punctures were performed in standard conditions[9] during the pre-drug period and at the time of maximum AMPT dose and assays were carried out by methods previously described[10,11]. The principal catabolite of dopamine (HVA), was reduced by 59%. The principal catabolite of serotonin 5-HIAA was increased in four of the five cases; however, these changes are not statistically significant. Because cerebrospinal fluid concentrations of monoamine catabolites seem to reflect central nervous system monoamine concentrations[12], these observations suggest that the AMPT in this study did produce a substantial reduction in brain catecholamines. The effect of AMPHe is presumably similar to that of AMPT, as it also is a potent inhibitor of tyrosine hydroxylase.

Our results indicate that central catecholamine-containing systems take part in the control of sleep in man. The finding of a substantial increase in REM sleep in the absence of a significant change in NREM suggests that these sleep states can be pharmacologically disassociated. These observations differ from the results observed in animal studies in which catecholamine synthesis was inhibited. There are no reports on the effects of AMPHe administration on animal sleep but AMPT had variable effects on REM sleep in rats[13,14] and cats[15,16], and decreased REM sleep in monkeys[17,18]. Conversely, administration of L-dopa to cats whose monoamine stores were previously depleted by reserpine, restored REM sleep[5]. In humans, L-dopa given with and without a peripheral decarboxylase inhibitor (MK 485) decreased REM sleep[4]:

in several patients, L-dopa at higher dosages also decreased NREM sleep.

In contrast, our previous studies with parachlorophenylalanine[1-3] and 5-hydroxytryptophan[19] indicate that in humans serotonin is intimately associated with the production of REM sleep, although a series of animal experiments suggest serotonin is associated with NREM[5,20-22].

We do not understand these apparent discrepancies between animal and human data, but they may be a result of differences in drug doses, route and period of administration or other parameters of experimental design[3]. It seems that in the human brain, however, the adrenergic and serotonergic brain systems act in opposite directions in the production of REM sleep, with the catecholamines decreasing, and serotonin augmenting, REM sleep.

Drugs were supplied by Dr Elmer Alpert, Merck Sharp and Dohme Co., Pennsylvania.

Induction of Mesodermal and Endodermal Structures and Primordial Germ Cells in *Triturus* Ectoderm by a Vegetalizing Factor from Chick Embryos

A VEGETALIZING protein isolated from 9 day old chicken embryos[1-3] and implanted into the blastocoel of an early *Triturus* gastrula[4] induces the ectoderm of the host embryo to form mesodermal tissues (muscle, notochord, renal tubes). Larger quantities of this highly purified factor cause the invaginated endoderm to exovaginate and spread over the induced ectoderm at the end of gastrulation. This may result from a change of cell affinities in the induced ectoderm[5]. In the exovagination series voluminous mesodermal and endodermal structures have been shown to develop from gastrula ectoderm under the influence of the implanted substance (U. K.-B., unpublished).

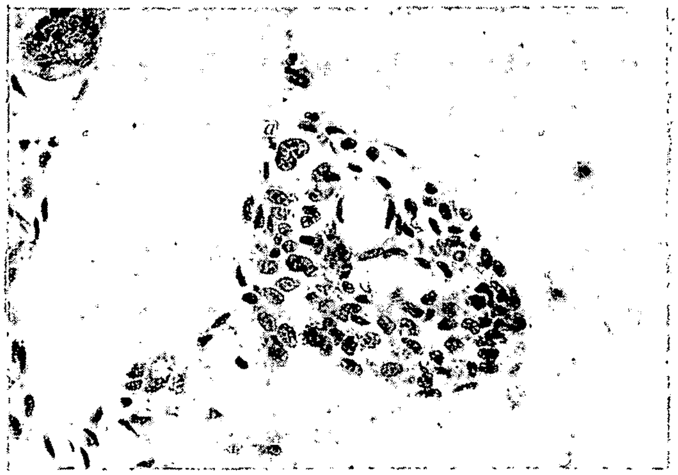

Fig. 1 Section through an induced gonad with an induced germ cell (*a*). Note the big cell with the typical potato-shaped nucleus. The explant was cultured for 41 days.

Effects of host embryos on the final outcome of the inductions are excluded if the inducer is tested on isolated gastrula ectoderm. To show the extent to which mesodermal and endodermal structures were induced by the factor, and to identify the induced endodermal organs, we used Holtfreter's sandwich technique[6]. Two pieces of gastrula ectoderm were sandwiched around a piece of the substance to be tested. Some explants were cultured at room temperature for 8–14 days, most of them for 3–7 weeks, to obtain good histological differentiation of endodermal organs. Most of the explants were spherical or cylindrical, compact and opaque and covered with endodermal epithelium.

As well as small unspecific neural structures, substantial but often poorly differentiated mesodermal and endodermal structures were induced in almost all cases. The induced mesodermal organs were notochord, muscle, renal tubes and sometimes mesenchym; the endodermal structures were mostly endodermal epithelium and intestine and, less frequently, liver, pancreas, stomach, oesophagus and pharynx. The relative frequency of all induced tissues varied between and within different experimental series, performed with various fractions of the vegetalizing factor. Though single explants consisted only of mesodermal tissues and others only of endodermal tissues and mesenteria, so far no fraction has induced mesodermal or endodermal organs exclusively. As well as these organotypic structures, in all series tissue complexes of large yolk-rich cells were found, which differed clearly from typical undifferentiated ectoderm. If the time of action of the inducing factor is shortened by removal of the implant after 1–24 h or if the factor is diluted, differentiation of the induced tissues improves.

Besides these organs and tissues, in eleven out of 125 explants primordial germ cells were observed for the first time as a result of induction. The primoridal germ cells were only found in explants which were cultured for at least 20 days. These especially large cells can be distinguished clearly from other cells by their histological appearance (Fig. 1). The explants in which primordial germ cells were found, contained also different mesodermal and endodermal tissues.

Both halves of the sandwich originate from gastrula ectoderm, so host germ cells, originating probably from lateral plate mesoderm[7,8], cannot have migrated into an induced germ ridge. The diagnosis of the primordial germ cells is based on their appearance and it has not been shown whether they are fertile. But the induction of these cells speaks strongly against the notion that the *keimbahn* is an absolute necessity for the development of germ cells in amphibians. Obviously germ cells can arise by regulatory mechanisms from somatic cells as do other cell types.

Probably only one factor induces the mesoderm–endoderm *anlage*, but the possibility that two factors are involved has not been excluded. All the observed differentiations including primordial germ cells certainly arise by secondary interactions.

Importance of Denitrification and Nitrate Reduction in Sediments to the Nitrogen Budgets of Lakes

DENITRIFICATION (biological conversion of nitrate and nitrite to nitrous oxide and molecular nitrogen) and nitrate reduction (assimilation of nitrate–nitrogen in microbial protoplasm) in lake sediments can play an important role in the nitrogen budgets of lakes. The hydrology of many lakes is such that ground water seepage through the floor constitutes a significant source of water income[1]. In such cases, nitrate in the incoming ground water must be considered when a nitrogen budget is calculated for the lake system. An excellent example is the estimate for Lake Mendota, Wisconsin[2], in which nitrate in seepage water constituted nearly 36% of the nitrogen added to the lake.

Lake sediments, being highly reduced and rich in organic matter, are ideal for denitrification. Fermentation gases emanating from lake sediments contain large volumes of molecular nitrogen, presumably biogenic in origin[3] and denitrifying microorganisms have been identified in marine and lake sediments (ref. 4 and unpublished results of R. L. Chen, D. R. K., J. G. Konrad, and A. J. Holding). Previous work in this laboratory[5] showed that the nitrate and nitrite contents of Lake Mendota sediment profiles increased with depth below the sediment surface, indicating that nitrate was moving through the profile and being reduced. But the only report attempting to quantitate the extent of denitrification and nitrate reduction in lake sediments is that of Goering and Dugdale[6] who in a laboratory incubation study with ^{15}N-labelled nitrate, found that nitrate added to mud–water samples from Smith Lake, Alaska, disappeared within 6 days and that reduction of nitrate to ammonia was insignificant compared with reduction to molecular nitrogen. Other work[7,8], has indicated, however, that significant nitrate reduction and denitrification will occur concurrently in anoxic lake waters.

We have evaluated the extent of denitrification and assimilatory nitrate reduction in the surface sediments of Lake Mendota. In June 1970, sediment samples were collected with an Eckman dredge and treated in the boat either with 5 ml./l. sediment of ^{15}N potassium nitrate solution (50.0 atom % ^{15}N) equivalent to 2.1 mg per l. nitrate–nitrogen on a volume basis, or with 5 ml. of distilled water (control samples). The treated sediment was added to 1 l. plastic bottles which were returned immediately to the lake bottom at the sampling site. The experimental sites were under 7 or 14 m of water and their temperatures were 18° C and 12° C; the dissolved oxygen contents of the water just above the sediment surface of the two sites were 9 and 7 mg/l. The bottles were left uncapped throughout the experiment. At 4, 8, 12 and 16 days after initiation of the experiment, two of the control bottles and two containing the treated sediment were carefully retrieved for analysis. Investigations conducted by lowering and immediately raising sterilized nitrate–nitrogen-treated sediment showed that loss of nitrogen by wash-out was negligible (average 99.8% recovery). Similar investigations showed that less than 1% per day of nitrate–nitrogen was lost by diffusion into the lake water.

Interstitial water ammonium, nitrate and nitrite and sediment exchangeable ammonium, as well as sediment organic nitrogen (the nitrogen in the sediment residue after exhaustive 2 M KCl extraction), were determined[5] and isotope ratioanalysis of interstitial and exchangeable ammonium-nitrogen and of sediment organic-nitrogen was conducted using a CEC 21-201 mass spectrometer by distillation and gas sample preparation methods[9,10]. Physical and chemical properties of Lake Mendota sediments have been described[5,11].

We found that nitrate disappeared rapidly from the sediment samples; only trace levels of nitrate existed 4 days after initiation of the experiment and nitrite did not accumulate. Interstitial and exchangeable ammonium-nitrogen levels in the 14 m sediment samples (13 and 184 p.p.m. respectively) were about four times higher than those in the 7 m sediment and remained fairly constant throughout the experiment at both sites. Also, these values did not differ significantly between the control and the treated sediment at each site.

The ^{15}N distribution data (Table 1) show that significant assimilatory nitrate reduction as well as denitrification was occurring in these sediments and that nitrogen turnover was quite rapid. Considerable incorporation of nitrate–nitrogen into microbial protoplasm occurred immediately on addition of nitrate, but in general the results reflect a microbial turnover of nitrogen coupled with sediment–water interchange. At both sites microbial immobilization was maximum at 4 days but was accompanied by considerable mineralization of protoplasm nitrogen. About 37% of the ^{15}N was recovered at 4 days, declining to about 20% at 16 days. The increase at 16 days was probably due to re-incorporation of soluble organic nitrogen compounds into microbial protoplasm, as soluble forms of nitrogen were not measured in our experiment. But this increase might be due to fixation of molecular ^{15}N produced during denitrification[12,13].

Table 1 Distribution of ^{15}N in Lake Mendota Sediment Samples at Various Times after Treatment with ^{15}N-labelled Potassium Nitrate

Time after initiation of experiment (days)	Recovery (%) of added ^{15}N in			
	7 m samples		14 m samples	
	Organic-N	Ammonium-N	Organic-N	Ammonium-N
0.4	8.1	0.3	14.3	1.5
4	30.8	6.9	29.1	7.6
8	9.3	8.0	13.5	6.9
12	5.2	6.1	9.2	3.8
16	14.5	4.7	14.4	5.4

These data point out the fact that denitrification and assimilatory nitrate reduction occur concurrently in sediments and must be considered when evaluating the nitrogen budget of lakes receiving nitrate from ground water. Lee[2] has estimated that Lake Mendota receives about 36% of its nitrogen from ground water seepage. This amounts to about 77,000 kg nitrogen per annum for the lake. It is clear that if this figure were reduced by using the 4 day results (37% of the nitrate–nitrogen immobilized and 63% denitrified), the ground water portion of the Lake Mendota nitrogen budget could be revised accordingly. Such a revision shows that the nitrogen contribution would decrease by 49,000 kg due solely to consideration of sediment denitrification. This illustrates the point that the fate of ground water nitrate in lake sediments must be considered when nitrogen budgets of seepage lakes are calculated.

This research was supported by the College of Agricultural and Life Sciences, University of Wisconsin, and by a grant from the Federal Water Quality Administration. We thank Professor R. H. Burris for use of the mass spectrometer and Mrs K. Chen for assistance in the analyses.

GENERAL

Uniform Distribution of Objects in a Homogeneous Field: Cities on a Plain

THE uniform distribution of objects in a homogenous field is familiar in all kinds of circumstances—atoms in liquids[1-3], fibrils in cells[4], hairs on insects[5,6] and mammals[7], stomata on leaves[8], trees in forests[9-10] and cities on plains[11,12]. In many of these circumstances the relative positions of the objects may be described by a radial distribution function. In what follows we shall show that such a function may be used to study the distribution of cities on a plain.

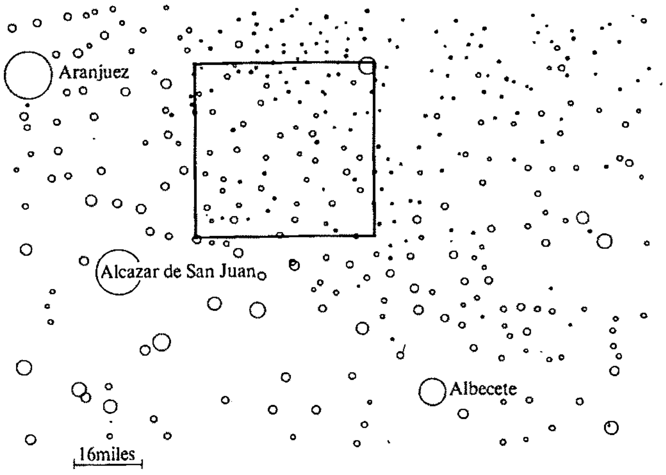

Fig. 1 A map of part of the Spanish Plateau lying south-east of Madrid, bounded by latitudes 0° 53′ W, 3° 41′ W and longitudes 38° 48′ N, 40° 16′ N. The radial distribution function of the cities lying in the square has been computed as described in the text. The locations of the towns were taken from the US Army Map Service topographic sheets of the Iberian Peninsula, 1 : 250,000, dated 1944.

Fig. 1 is a map of part of the Spanish Plateau lying south-east of Madrid and bounded by latitudes 0° 53′ W, 3° 41′ W and longitudes 38° 48′ N, 40° 16′ N. This area is homogeneous in climate, physiography, transportation, population density and economy. The towns are represented by circles whose radius is an approximate measure of physical extent[13]. We have chosen for analysis the 40 mile square centred at latitude 2° 30′ W and longitude 39° 47′ N which is especially homogeneous in town size and density.

The radial distribution function $g(R)$ is defined as the probability that a structure will be in a unit area a distance R away from an arbitrary structure, divided by the number probability density. It may be computed for the town lying in the square in Fig. 1 in the following way. Place each town in turn at the origin and surround it by a series of concentric circles spaced at a distance of $\Delta R = 1$ mile. Determine the area, $K_i(R)$ (lying wholly within the square in Fig. 1) of the annulus whose boundaries are at distances of $(R - \Delta R/2)$ and $(R + \Delta R/2)$ from town i. Let the number of towns lying within this annulus be N_i (R). If N is the total number of towns in the square and K is the area of the square, then

$$g(R) = \frac{N(R)}{\rho K(R)}$$

where

$$N(R) = \sum_{i=1}^{N} N_i(R)$$

$$K(R) = \sum_{i=1}^{N} K_i(R)$$

$$\rho = \frac{N}{K}$$

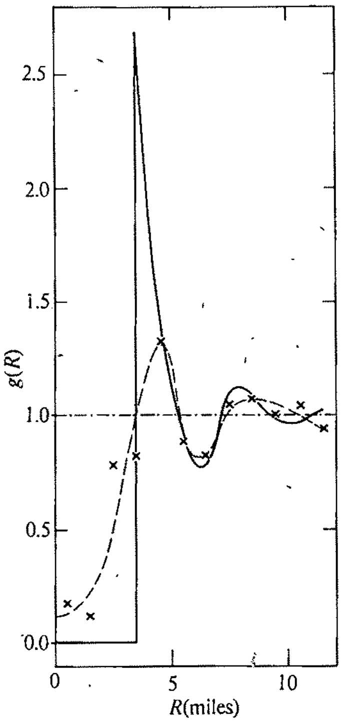

Fig. 2 The radial distribution function computed for the towns in the square in Fig. 1 (- - -), for a totally random distribution (—.—.—), and for a random distribution of hard-core disks with $\bar{\rho}=0.5$ and $d=3.46$ miles (——).

In Fig. 2 the computed distribution function is indicated by the dashed curve drawn through the crosses which represent the points at which the determination was made; the radial distribution function for a random distribution is depicted by the dashed-dot line in Fig. 2.

The diminished density near the origin and the subsequent damped oscillations in density are characteristic of distributions in which objects are fundamentally randomly dispersed, but are subjected to repulsive interactions which tend to diminish the probability of finding two objects close to each other. If the distribution is formed by a dynamic process which guarantees that the distribution is maximally random subject to the constraints of the interparticle interactions, then the theoretical concepts developed in the study of the statistical mechanics of equilibrium liquids may be applied.

An example is useful. Assume that the towns are randomly distributed subject only to the constraint that no two town centres may be closer than a distance, d. Similar models have been proposed as prototypes for spatial interaction and pattern formation in biological systems[6,7,9]. Because the resulting distribution also arises in the hard-core model of classical liquids at equilibrium[2,3], the radial distribution functions for such distributions have been intensively studied. The results are tabulated[3] for different relative packing densities, $\bar{\rho}$, where $\bar{\rho}$ is the number density divided by the maximum close packed hard-core density, and is given by

$$\bar{\rho} = \frac{\sqrt{3}}{2}\,\rho\, d^2$$

The best agreement is given when $\bar{\rho}=0.5$, which corresponds to a hard-core town diameter of $d=3.46$ miles (solid line in Fig. 2). Although there is qualitative agreement, the hard-core interaction is too stringent to give detailed quantitative agreement with the experimental results. A more realistic interaction between towns would be graded, in which the probability of finding two towns close together would be low, but would continuously increase as the distance between the towns increased. This is what would be expected from the geographic theory of central places[11,12]. Lawrence, in a study of hair placement in *Oncopeltus*, has hypothesized the existence of a very similar repulsive interaction which leads to the uniform distribution of hairs[6].

No matter what system is considered, this hypothesized repulsive field plays much the same role as the intermolecular potential in the theory of liquids. If the distribution of structures is maximally random subject to the constraints imposed by this repulsive field, then the equations developed in statistical mechanics may be applied. It is possible to compute theoretical radial distribution curves for a given hypothesized field (ref. 1, chapter 5) and also to determine, approximately, the interaction between structures if the radial distribution function is known (ref. 1, page 80). Future work may characterize the hypothesized repulsive fields and explore their physical, biological and social origins in those diverse disciplines where uniform distributions are observed.

L. G. thanks Professor H. C. Longuet-Higgins for his help and the US Public Health Service, National Institute of Health, for financial support. The data were assembled by G. Aspbury during tenure of a National Science Foundation grant.

BOOK REVIEWS

Oppenheimer in Dock

The Oppenheimer Case, Security on Trial. By Philip M. Stern. Pp. xiv+591. (Rupert Hart-Davis: London, May 1971.) £3.50.

"THIS began as a book about a security case," writes Mr Stern in his preface. "It ended as a book about the security system. The case is now history. The system is still with us." A baleful opening for anybody old enough to remember the witch-hunting McCarthy period in the United States and the accusing of J. Robert Oppenheimer, theoretical physicist, so-called father of the atomic bomb, of being a Soviet agent. And not encouraging for anybody young who gives thought to the secret dossier-collecting activities of security organizations today—an estimated 14 million dossiers totted up by the US Department of Defense, 42 million by an American private investigation agency. . . . Mr Stern describes them: "Permanent collections of secret information, many of which may contain misinformation that the 'subject' has no way of rebutting or correcting—because he is not allowed access to it."

In the case of Robert Oppenheimer there were 3,000 pages of secret material, from which large black notebooks were made and circulated in advance of the hearings not just to the counsel who was going to lead the prosecution, but also to the judges—a tribunal called the Gray Board, set up by the US Atomic Energy Commission. So, by a reversal of the American "blank pad" (for the judges) rule in trials at law, Oppenheimer had laid on him from the start the burden of proving his own innocence.

Oppenheimer and his counsel were not allowed to see what was in the notebooks; and "for reasons of security" his counsel was sent out of the court while certain extracts were dealt with—not that this stopped the subsequent reading out in open court by the prosecution counsel of some of those which Oppenheimer's counsel had been denied. So Oppenheimer had to prove his own innocence in the face of accusatory material known to the judges that was never revealed in full to his side. Furthermore, several of the principal charges against him, including a crucial security charge, had been taken into account when he was given his Q-clearance seven years earlier; so he was in effect being "tried" twice over for the same thing. Furthermore, some of his "offences" were, at the time he was supposed to have committed them, not unlawful. . . . Security on trial indeed! If there was one thing security was *not*, it was on trial. Safe behind closed doors, it totally evaded any critical, let alone judicial, investigation of its own processes and nature.

The history of the case is hair-raising. With an unforced combination of the historian's organization of fact and the novelist's interest in people, Mr Stern tells it brilliantly: each of the 500 pages simply has to be read. In the last fifty pages, when he specifically turns his attention to "security on trial", it loses a little of its coherence and grip, but that is a minor defect. He begins his story in 1936, when the young Oppenheimer, rich, cultivated, solitary-natured bachelor son of a Jewish East Coast family joined the Faculty of the University of California at Berkeley; and began in the "liberal" fashion of the times to associate with local Left wing organizations, near-Communists, Communists. With a sharp pertinence, Mr Stern remarks that when Oppenheimer was "tried" in 1954 these associations were set by his accusers and judges entirely against the current cold war situation of the early 1950s, and never judged against the historical background in which they occurred. To be fair to his accusers and judges, when reading about them now, one has to avoid the comparable trap of judging their behaviour entirely against the *détente* ambience of today, forgetting the paranoia and hysteria which was gripping the United States (not to mention the Soviet Union) then.

Throughout his career Oppenheimer showed an intellectual brilliance which permanently captivated his friends and his followers—and roused permanent hatred and alarm in the men he made his enemies. In his theoretical physics, though, he never made any fundamental discoveries: he was the quintessential solver of other people's problems rather than creator of his own. At first sight it seems odd that a scientist of this kind should succeed so astonishingly as the director of the scientists at the Los Alamos weapons laboratory who actually were making discoveries. Even odder that a man of his physical and temperamental type—essentially ectomorphic, fine-drawn, a creature of quick, nervous apprehensions—should be so masterful in the hurly-burly of power. And should continue to be so, later on, when from the eminence of the Princeton Institute for Advanced Study he engaged in controversy over whether the hydrogen bomb should be developed, and then whether it should be made the centrepiece of US defence—controversy in which he made an enemy of Edward Teller, father of the hydrogen bomb, and, more fatally, aroused the hatred of the US Strategic Air Command.

In fact the Gray Board's final judgment was that Oppenheimer "seemed to have had a high degree of discretion, reflecting an unusual ability to keep to himself vital secrets." Did most of them, and successive ratifiers of the verdict, ending with the Atomic Energy Commissioners and then the Government, bring him to his knees by revoking his security clearance really out of fear that at some future date he would give away secrets to the Russians? Or, Mr Stern asks: "Would Oppenheimer have been charged as a security risk if he had not held controversial opinions; if he had not advocated them with extraordinary persuasiveness, if he had not aroused (and on occasion sorely offended) persons in high places?"

A very good question. Given the answer is "No", it is disappointing not to find oneself whole-hearted about Oppenheimer as a man. It seems that in the last resort he lacked some kind of ballast—moral ballast, psychological ballast, possibly even intellectual ballast. Throughout the book examples abound to such an extent that it cannot be ignored. There was something very lightweight about the way he got himself mixed up with Communists before the Second World War. When he saw the first atomic device exploded he murmured a poetic quotation from the *Bhagavad-Gita.* And after having been so appalled by the destructive possibilities of the hydrogen bomb that he wanted America to forswear working on it and to get the mutual consent of Russia to do the same (what a hope!)—after all that he said, when Teller triumphantly showed it could be made, that it was "so technically sweet that you could not argue about it". So technically sweet. . . There is a point at which lightness of weight, absence of ballast, can become faintly sickening. Yet it must be stressed that men who knew him, men such as I. I. Rabi and Hans Bethe, possessors of great ballast themselves, could reiterate years later their admiration and respect for him as a whole man. Mr Stern's attitude towards him, I may say, is impeccably detached and fair.

However, nobody's reading of Oppenheimer's character solves the enigma which overhangs the crucial security charge against him. Sometime in January or February 1943, Oppenheimer and his friend Haakon Chevalier were making martinis in Oppenheimer's kitchen. "There is no dispute over the fact," Mr Stern records, "that Chevalier reported that Eltenton said he had means of getting technical information to the Russians. It is also agreed that Oppenheimer made it immediately clear that he would have no part in such an affair." The astonishing, inexplicable thing is that Oppenheimer later gave different accounts of the incident; and that in particular he gave an egregiously untruthful account to a security agent called Boris T. Pash, in which he refused to disclose Chevalier's name while saying that several other men were involved—a cock-and-bull story that was much more injurious to himself and Chevalier than the truth, and which at his "trial" he allowed to be called "a tissue of lies". It was an incredible thing to do; and when asked why he did it, he replied: "Because I was an idiot." It did him critical harm.

What could be the explanation? Nobody among his friends or his enemies has found a credible answer by looking at the character of Oppenheimer. Is it to be found, I propose, by looking instead at the character of the incident? Is that kind of interrogation liable to induce that kind of aberration? Oppenheimer's egregious performance *vis-à-vis* Colonel Pash was recorded through a hidden microphone and it makes disturbing reading—because of the peculiar intimacy existing between interrogator and interrogated. A fulsome, ingratiating duplicity on the interrogator's side; a fulsome, yielding over-accord on the interrogated's—"God bless you," he says at the end of it. One wants to turn one's head away . . . But that would mean turning one's head away from a very serious matter, where security really on trial could well be required to prove its case. The matter at issue is not the unnaturalness of the intimacy: it is the trustworthiness of the situation—its trustworthiness not to throw a man off balance, not to produce, while he is in it, almost a personality change. Is the solution to the Oppenheimer enigma not that he was an idiot, but that such interrogations are liable to bring idiocies to a man's lips? Really on trial, security is not invulnerable.

WILLIAM COOPER

Early Trains

Civil Engineering: Railways. By Bryan Morgan. Pp. xvi+176+45 Photographs. (Longman: London, April 1971.) £2.96.

THE admirable series of studies of industrial archaeology edited by Mr. L. T. C. Rolt has now reached railways. Wisely, he has decided that the subject is too big to be comprehended in a single volume, such as the one he wrote himself on *Navigable Waterways*, and that it must be treated in two. This book is therefore complemented by another on mechanical engineering, written by Mr J. H. Snell.

Mr Morgan's study is comprehensive, clearly arranged, and most pleasantly written. Within the modest limits enforced on him he packs a great deal of information and lively comment. He rightly stresses the importance of the early years of railway building, before the locomotive appeared and during its primitive, fitful development. He pays proper attention to the track, commenting with a severity that is well justified on the treatment usually accorded to "these unglamorous lengths of scrap iron" in museums, and taking trouble to explain the reasons that lay behind the adoption of different forms of rail, sleeper, and ballast. His illustrations and diagrams are a well integrated adjunct to his text.

The book has some faults. Its proportions may be criticized here and there. Scotland receives on the whole scanty attention. Of more than a hundred structures mentioned in the gazetteer at the end of the book, only four lie north of the border. Perhaps more serious, more than four-fifths of the text is devoted to the period before 1865. That was indeed the heroic age of railway building in this country, but notable work has been performed since, which is passed over here: for example, the extraordinary series of bridges, in Staffordshire blue brick, erected over the Midland Railway's line south of Kettering in the 1880s and 1890s, where the engineers were treating the bricks in an almost plastic way that seems to anticipate the handling of reinforced concrete in the twentieth century. And by way of a final criticism it must be said that there are rather more small mistakes here than there ought to be: obvious misprints uncorrected, names mis-spelt and places wrongly cited—Ashburton for Ashton, for example. It was not the North Midland Company that tried to reach Manchester (page 117); nor was Tite the architect of the station at Shrewsbury (page ix).

These small blemishes can be rectified when the book goes into a second edition. It deserves to be kept in print for a long time as an excellent introduction to its subject, which will not lose its value. Mr Morgan is generous in searching out distinction among his engineers and architects, whether in pioneering forms and techniques or in aesthetic sensibility, and he communicates his enthusiasm so attractively that he will inspire his readers to follow him in the direction of inquiry he has laid down. His book achieves its purpose very well indeed.

JACK SIMMONS

Röntgen Revealed

The Life of Wilhelm-Conrad Röntgen. By W. R. Niske. Pp. xi+355. (University of Arizona: Tucson and Arizona April 19, 1971.) $8.50.

WHEN in 1895 Röntgen made his great discovery he was already fifty years old, and the rest of his life was in a sense an anticlimax; it seems that he genuinely hated fame and publicity, and regretted his move from Würzburg, where he had been happy, to Munich, where he was not. After his three papers describing the phenomena of the X-rays, he played no important part in the practical development of the apparatus or in the explanation of the phenomena; in this he reminds one of Volta, who made his discovery at much the same age. It is clear from this biography that Röntgen's discovery, while unexpected, was in no sense an accident. He had been carefully trained under A. E. E. Kundt to make very accurate determinations of physical quantities; first investigating the specific heats of gases, and then studying electromagnetism, and the physical properties of crystals. His academic position—he had held a chair at Giessen before being called to Würzburg to follow Kohlrausch—and his reputation for sober accuracy ensured that his preliminary paper on X-rays was taken seriously.

The study of cathode rays was an obvious field for investigation; mercury pumps were available to give very low pressures, and it seems that others had noticed fluorescence near cathode ray tubes and fogging of photographic plates, but had not seriously investigated the matter. In November and December 1895, Röntgen investigated the X-rays in an extremely capable manner, proving that the effects could not be due to cathode rays, and taking a number of X-ray photographs. He submitted his preliminary paper on December 28, 1895; it was published with a rapidity that moderns might envy, for the offprints were ready to be sent out on new year's day 1896. Röntgen was transformed from a man with a high reputation within his field into a celebrity; and was in 1901 awarded the first Nobel Prize for Physics.

Reading this sympathetic biography, one feels that Röntgen had somehow got out of his depth; like Faraday, he had the "ability to improvise laboratory equipment, which enabled him to make observations that less skilled men were unable to do", but we find little evidence that like Faraday he was a solitary voyager in strange seas of thought. His orderly life, with the spring and summer vacations spent in Italy and Switzerland, does not have that appearance of complete devotion to the struggle with the mysteries of nature which characterizes those few scientists of the first rank. Röntgen's example can encourage us all, for he seems to have been a rather ordinary scientist who made an extraordinary discovery; and this biography is valuable in bringing before us such a man and casting light on his times. In spite of a tendency to degenerate into travelogue, the book is readable and interesting; we encounter both the crusty and forbidding professor and the shy man at ease holidaying with his friends. We even find him in 1888 complaining of the declining number of students because for scientists "the outlook is gloomy".

D. M. KNIGHT

Illuminating Letters

The Born Einstein Letters. By M. Born, Translated by I. Born. Pp. xi+240+4 plates. (Macmillan: London and Basingstoke, May 1971.) £3.85.

THIS volume consists of 120 letters between Einstein and Max and Hedwig Born, the first written by Einstein in 1916 as the General Theory was breaking on the world, the last by Born in January 1955, as both men became involved in the events leading up to the Russell–Einstein Manifesto. Commentaries written by Born in 1965, when he was already in his eighties, fill in details, add later judgments, and provide a background to the men, and the occasional woman, who lived through the dramatic era of physics between the two world wars.

The principal scientific interest in the correspondence lies of course in the long debate between the two men, and most, although not quite all, of their long discussions can be followed here. Their first meeting was at Salzburg in 1909 when Einstein, justy thirty, giving his first big invited paper, declared "a profound change in our views of the nature and constitution of light" to be indispensable. Born himself finds it hard to believe that he did not correspond with Einstein when working on the latter's theory of specific heats three years later.

The letters touch on the anti-Einstein movement of the early 1920s in Germany and on the confrontation between Einstein and Lenard at Bad Nauheim in 1920, in some ways comparable with the Wilberforce–Huxley dispute at Oxford in 1860. (Interestingly enough, no full verbatim account of either seems to have survived.) They add to the material on the birth of quantum mechanics already available in the Einstein–Sommerfeld letters and in the *Letters on Wave Mechanics* by Einstein, Schroedinger, Planck and Lorentz published four years ago. And they carry the debate on quantum mechanics into the 1950s.

Yet their interest does not lie solely in the contemporary comments of two masters, made as the new physics evolved. There is also their parallel reaction to events in Germany, to the birth of nuclear weapons and to the increased responsibility of scientists for the ways in which their work is utilized. While Einstein signed the momentous letter to Roosevelt which helped launch the American atomic effort, Born found the idea of nuclear weapons so distasteful that he avoided personal involvement and tried—unsuccessfully—to dissuade one of his workers in Edinburgh from joining the British effort: Klaus Fuchs. And when Born returned from Britain to Germany after the Second World War, Einstein noted that he was going back "to the land of the mass-murderers of our kinsmen".

There is a third interest in the correspondence, in some ways almost as important as the light cast on the argument between the standard-bearers for two opposing scientific views. Both Max Born and Albert Einstein reveal in these letters not only great intellects, but a warmth and humanity sometimes considered—rightly or wrongly—to be rare among scientists.

R. W. CLARK

Physics Performed

Physics: Demonstration Experiments. Edited by Harry F. Meiners. Vol. 1: Mechanics and Wave Motion. Pp. x+1–654. Vol. 2: Heat, Electricity and Magnetism, Optics, Atomic and Nuclear Physics. Pp. iv+655–1395+36. (Ronald: New York, 1970.) $30 per set.

ONE of the opening chapters of the two volumes entitled *Physics, Demonstration Experiments* was written by the late Sir Lawrence Bragg. His association alone makes these two books not just another pair of books on physics demonstrations but an inspiration—an inspiration to all those who wish to make a physics course in school or at university really alive.

The two volumes are divided into a subject classification of, volume I: *Mechanics and Wave Motion*, and volume II: *Heat, Electricity and Magnetism, Optics, Atomic and Nuclear Physics.* A great bonus in each book is an additional chapter: in volume I the whole philosophy and art of the use of demonstrations to teach physics is discussed, while in volume II the additional chapter discusses the use of closed circuit television, overhead projectors, stroboscopic effects and other modern teaching devices which are now becoming commonplace in the lecture room.

Not since *Demonstration Experiments in Physics* by R. M. Sutton has there appeared a work which deals with the subject so well. Professor Harry F. Meiners, the editor, has gathered the cream of international physics demonstration techniques and methods into these two volumes. Contributions from the United States, Britain, Israel and Russia are all included, together with many others.

From this mine of information for teachers and lecturers, it would be impossible to summarize, or even give a list of the demonstrations in these volumes, which together add up to 1,400 pages. It is easier to say that from a simple demonstration of shadow projection to solid state physics or the application of a laser, all are included.

On reading these books the complexity of some of the apparatus is a little worrying until it is realized that apart from the description of the demonstration in the text, full constructional details and drawings, almost down to the last nut and bolt, are given in an appendix at the end of each volume. If commercial apparatus is used a list of suppliers or manufacturers is given. This publication was sponsored by the American Association of Physics Teachers, and being American, most of the suppliers are American. This need not deter the English reader as equivalent equipment is obtainable in this country.

These books, which have some 2,000 photographs as well as line drawings, would be excellent additions to any Science Library.

To conclude, Sir Lawrence Bragg's advice to a lecturer was to not just talk about science, but, if possible, to demonstrate it. These books show the way.

W. A. COATES

Anaesthetic Collection

International Encyclopedia of Pharmacology and Therapeutics. Section 8, Vol. 1: Local Anesthetics. Section edited by P. Lechat. Pp. ix+377. (Pergamon: Oxford and New York, April 1971.) £6; $16.

THIS volume of the *International Encyclopedia of Pharmacology and Therapeutics* comprises ten chapters written by internationally known authors, two of whom are now unfortunately deceased. It amply justifies the title encyclopaedia, and covers in exceptional detail the various aspects of local anaesthetics, which range from historical development to current clinical application, and deals with structure–activity relations, mode of action, pharmacological properties and their modification, methods for comparison of activity and finally the toxicity and side effects of these substances.

Each chapter is very fully referenced and the individual authors are to be complimented on the fullness of their text which is amply illustrated with photographs, diagrams and tables, although the first chapter on the historical development of local anaesthesia tends toward over illustration. A strong emphasis is placed throughout the book on historical aspects and early work, and in several chapters careful reading is required, as the general theme passes through a maze of previous ideas, experimentation and thought, before more recent concepts are expounded and further compared. However, even though the book is often an exposition of previous and current work, an attempt is made when appropriate to provide critical assessment.

The part local anaesthetics play in the temporary alleviation of pain during surgery is well known, and the continuing search for newer and better agents serves to illustrate the importance of these drugs and the fact that even those of more recent development suffer from certain clinical deficiencies, a point stressed in the final chapter. Much knowledge has, however, still to be gleaned and this textbook with its well documented account of past development, the deficiencies and properties of current drugs, and the experimental techniques used for the assessment of new drugs, should do much to stimulate further interest in the subject and provide an excellent comprehensive reference and reading text, not only for pharmacologists, both graduate and undergraduate, but anyone with an interest in local anaesthetics.

A. J. DUXBURY

Pesticides Around Us

Pesticides in the Environment. By Robert White-Stevens. Pp. xv+270. (Marcel Dekker: New York, June 1971.) $23.50.

THE current widespread interest in all forms of environmental pollution by chemicals ensures an extensive potential audience for any work with the title *Pesticides in our Environment.* This is the first of five books to be published as parts of two volumes under this title. This first part of the full volume, and the part yet to be published, together deal with the more theoretical aspects of pesticidal chemicals, whereas the second volume will deal with the more practical problems of handling pesticides in the environment. The editor of the series, Dr R. H. White-Stevens, now heads the Bureau of Conservation and Environmental Science in New Jersey, and has had considerable experience of research in the agricultural chemical field.

The professed aim of the series, as stated by the editor, is to present in authentic objective terms, the properties, functions, utility and contributions of pesticidal chemicals to human welfare, and to provide data that will enable the optimum combination of efficacy, safety, reliability, economy and environmental improvement to be attained. Unfortunately, it is impossible to judge accurately from this first book in the series whether these ambitious aims will be achieved when both volumes have been published.

This book comprises three sections all written by well qualified authors. They discuss the chemistry and biology of pesticides (R. L. Metcalf), the metabolism of insecticides and fungicides (T. R. Fukuto and J. J. Sims) and the metabolism of herbicides (J. E. Loeffler and J. van Overbeek). The chapters are well written and serve as an excellent, chemically oriented, introductory text and reference work on pesticides. However, they are written so as to appeal more to practising scientists than to the layman, at whom they also profess to be aimed. It is a great pity that the book lacks an index, because this greatly lessens its value as a rapid reference text. One other shortcoming is that, if the discussion is to be really pertinent to the title of the series, the relative persistence of pesticides should be discussed, but it is not; perhaps this omission will be rectified in the second volume of this series. However, these criticisms are minor and do not detract from any appreciation of the efficient and workman-like way in which the sections are written.

The standard of production is good and the layout pleasing and suitable for the subject matter, but the price will probably prove a considerable obstacle to many potential readers. There is no doubt that this book is a useful new addition to the literature on pesticides, providing information that may not be readily available elsewhere.

CLIVE A. EDWARDS

Feathered Friends

Man and Birds. By R. K. Murton. (The New Naturalist.) Pp. xx+363 +32 plates. (Collins: London, May 1971.) £2.50.

CONFUSINGLY, an earlier volume in this New Naturalist series, by E. M. Nicholson, appeared under the title of *Birds and Men.* However, while Nicholson in 1951 could point out how little was known about the precise relationships of birds and men, Murton can show how much has been discovered. It is salutary that less than one-sixth of the references cited here were available to Nicholson when he wrote his book twenty years ago, and many of these are merely old, unquantitative records showing that a particular problem is not new. To quote but one example, Nicholson does not mention the oyster-catcher, which is thought by some to have a serious effect on the cockle industry; twenty years later, after the Ministry of Agriculture, Fisheries and Food has spent perhaps £100,000 investigating the matter, Murton can devote thirteen pages to the problem based on many published works, mostly dating from about 1957.

Man and Birds contains an amount of theoretical population biology which the amateur may find somewhat heavy going, particularly the second and third chapters (on ecological considerations and predators and prey). Notwithstanding this, there are few places where such matters have been so forcefully put. The fundamental concept of population ecology is probably that of density dependent mortality; at certain seasons of the year, animals, as a result of reproduction, are usually commoner than some resources that they need. A number (usually relatively large) of them must die as a result of competition for the resource. If man kills a proportion of the animals it does not follow that breeding numbers will be reduced; usually they are not because individuals which would otherwise have died in competition with their fellows are now able to survive in place of them. This point, together with the rapid rate of increase (or recovery), when birds are scarcer than usual, is still often overlooked by people who seek to control or to protect birds.

Some 180 pages of the book cover, by species, the birds which impinge on man's activities; the section is of great value, for the author clearly knows his literature. Two final chapters cover birds and industrial man (including fouling of buildings and bird strikes and aircraft), and wildlife management (future methods of control, such as tape recorded alarm calls and distasteful compounds).

This is a very valuable review which will be widely read. However, since it was written for a market which is, to some extent, "popular" it could have been more simply written, and fewer digressions into methodology (and subjects such as photoperiodic physiology) would have made it more concise. So vast is the scope that no two people would agree on what should be included, but I would have included more about man's affect on the birds. Even the most ardent bird-hater must appreciate that massive mortality of birds may give him an early warning of something that he is doing which may ultimately back-fire on himself; large losses of sea birds, particularly the auks, are potentially important from this aspect. Also there is relatively little about bird problems outside Europe. The small finch *Quelea* in Africa does perhaps many times more damage than any birds in Europe. Problems in North and South America and elsewhere on rice-eating birds have been studied in some detail as have those of birds in vineyards, but these are barely mentioned.

CHRISTOPHER PERRINS

CORRESPONDENCE

Freedom of Scepticism

SIR,—In his letter (*Nature*, **232**, 355; 1971) Dr Higginson raises a number of points that are perhaps representative of a certain kind of contemporary view and which I shall endeavour to answer.

All of us are influenced by a respect for the authority of properly qualified scientists and by the beliefs of our colleagues. But it is a voluntary alignment and every man must have the right to re-examine sceptically the verities of conventional wisdom.

There are also many well-qualified scientists who set constraints on these freedoms and react unfavourably when the expression of scepticism generates heat rather than light. But public disclosures are the primary means by which we mutually regulate our affairs! Friction may be generated by this exchange. But I believe this comes about when the sceptic is not afforded the same courtesies as is the true believer, and Dr Higginson's letter is a case in point.

For instance, there exist well-documented critiques of most of the published evidence concerning smoking and lung cancer and other health matters—critiques, moreover, that appeared in respected and rigorously reviewed journals. In the past few months articles have appeared by Dr Yerushalmy, evaluating the data on the effect of smoking on the weight and growth of infants born to mothers who smoke (*Amer. J. Epidemiol.*, **93**, 443; 1971), and carefully re-examining and rejecting the claim advanced by a number of prestigious (and unreviewed) US Government reports that smokers suffer from a larger incidence of morbidity than do nonsmokers (*J. Amer. Stat. Assoc.*, **66**, 251; 1971). The trouble, however, is that Dr Higginson does not care to acquaint himself with the literature of dissent or even acknowledge its existence (although demanding that we document our objections—*again?*).

Or Dr Higginson speaks of the "widely explored area of cigarettes and lung cancer"; but is this impression of such a thorough exploration not created in part, too, because Dr Hammond and others have published over and over again their findings based on a single study? Dr Hammond has produced over a dozen published papers, besides innumerable talks and testimonials, all based on his confidential 1960 population survey. (His procedures had been felt to be inadequate by a number of statisticians who, incidentally, have published their criticisms all along.)

On the other hand, how often can one publish a critical review?

Again, Dr Higginson betrays his extreme displeasure by equating a courteous request by fellow investigators to meet and discuss the possibility of a public review of data, including assurances of all possible safeguards, with a "smear" and hints that the perpetrator of this dark deed somehow is motivated by "the grant reported to have been made recently to his university by certain industrial interests". (I am sure that if Dr Higginson will address a proper request to the administration of Washington University and specify which industrial interest he seeks to expose, this information will be made available to him.)

I understand that centuries ago a number of members of the faculty of Oxford University protested the establishment of laboratories for students. Being men of the highest repute and integrity, they saw no need for students to verify their claims about what was observed in their laboratories at the cost of great bother to them and needless expense to the university. But this took place many years ago; and even at Oxford the faculty has proved to be wrong occasionally.

Yours faithfully,

T. D. H. STERLING

Weaned from Confusion

SIR,—"The cow suckles the calf" and "the calf sucks the cow" are descriptions of the one phenomenon, so clear that there should be no difficulty; but there is. During recent fairly extensive reading about this and related topics, I was sometimes so confused by the haphazard use of the two verbs that I was at a loss to know who had been doing what to whom.

Among this reading was a letter[1] written by Cowie and his colleagues and published by you in 1951, which must evidently be blamed for some of the confusion, since some authors have quoted it as their authority for writing "suckle" when they have meant "suck". Others have muddled the words quite indiscriminately and still others have adopted standard usage. Is it too late to agree that the language of the Psalms, St Matthew, Shakespeare and Lamb is good enough and that we should all use it to record our observations and express our thoughts as clearly as we can?

Yours faithfully,

F. R. SPRATLING

School of Veterinary Medicine,
Cambridge

Alluvial Gold

SIR,—In the issue of *Nature* for July 23 (**232**, 214; 1971) there is a brief item on the proposed exploration for gold and copper by Rio Tinto Zinc in the Mawddach estuary and Snowdonia. I was particularly interested in the statement that RTZ plans to sift or dredge the sediment of the estuary for alluvial gold.

During my doctoral studies from 1961 to 1964, I had occasion to study in detail the sediment from the estuary proper, from the freshwater rivers running into it, and from the offshore area in the immediate vicinity. In particular, I examined the texture and the accessory minerals of the sediments. The results of this examination showed significant similarities in the sediments from the estuary and the offshore environments and significant differences in the sediments from these two areas and that from the freshwater rivers (Mawddach and Wnion). This led me to the conclusion that ". . . it is very probable that the offshore areas are the major source for the sediment in the estuary, at least as far up as Penmaenpool . . ."[1]. Put more simply, this means that most of the sand in the Mawddach estuary is brought in from the sea and is *not* derived through the erosion of the gold-bearing rocks near Bontddu.

Also, as part of the overall study, I examined the records of the Barmouth Harbour Trust in the National Library of Wales, Aberystwyth. These records showed that a European firm had been granted a concession to dredge for gold in the Mawddach estuary just prior to World War II, but that the firm had abandoned the project as uneconomic.

The success of any dredging projects for alluvial gold in the Mawddach estuary, or even the need for preliminary exploration, are therefore questionable.

Yours faithfully,

R. M. McMULLEN

Obituary

Sir Lawrence Bragg

Fig. 1 William Lawrence Bragg as a young graduate at Cambridge. (By courtesy of the Nobel Foundation.)

SIR LAWRENCE BRAGG, who died on July 1 aged 81, had the unique distinction of having himself created the science to which he devoted his life's work, and lived long enough to experience its revolutionary impact, first on inorganic chemistry and mineralogy, then on metallurgy, and finally on organic chemistry and biochemistry. At the same time X-ray analysis itself advanced from the ingenious puzzle-solving of the early pioneers to the almost blindfold automation of the present day.

Röntgen discovered X-rays when Bragg was five years old, and von Laue, Friedrich and Knipping demonstrated X-ray diffraction by crystals in the spring of 1912, when Bragg was taking his physics degree at Cambridge (Fig. 1). Von Laue, who had predicted the effect, also succeeded in developing a theory of scattering from a three dimensional lattice, but he assumed that the crystal of zincblende used for diffraction had a primitive cubic lattice, and therefore could not explain why spots corresponding to certain indices were present while others with closely related indices were absent. He speculated whether the diffraction effects had arisen from fluorescence excited in the atoms of the crystal by the "aperiodic pulses" of the primary radiation or whether five prominent wavelengths pre-existing in the primary radiation had been separated out to produce the different diffraction spots.

Bragg's father, then Professor of Physics at Leeds, heard of the German work in the summer of 1912 and discussed it with his son, who set about re-interpreting the X-ray pictures of zincblende published by the Munich group. Within a few weeks he presented the correct answer to a meeting of the Cambridge Philosophical Society. The German group had noticed that spots which were round when their photographic plate was close to the crystal became elliptical as the plate was moved further away. By a remarkable feat of imaginative insight Bragg realized that such a focusing effect would arise if the X-rays were reflected by successive atomic planes (Fig. 2), and he reformulated von Laue's conditions for diffraction into what became known as Bragg's Law, which gives a direct relationship between the crystal structure and its diffraction pattern. Bragg then recognized that sets of parallel lattice planes would select from a continuous spectrum (or pulse, as he called it) those wavelengths which corresponded to integral multiples of the path difference between reflexions from successive atomic planes, so that each Laue spot would be made up of several harmonics of some selected wavelength. Finally, he demonstrated that the presence of spots with certain combinations of indices, and the absence of others, could be accounted for by assuming a face-centred rather than a primitive cubic lattice.

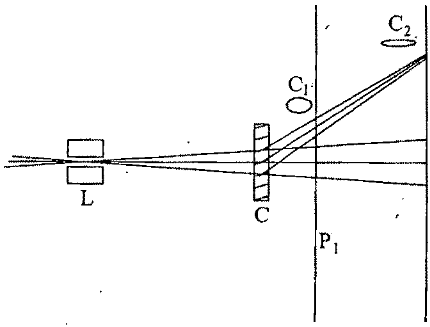

Fig. 2 Bragg's interpretation of the focusing of the diffracted spots observed by von Laue, Friedrich and Knipping which led to the formulation of Bragg's law: $n\lambda = 2d\sin\theta$. L, Lead screen; C, crystal; P_1P_2, positions of photographic plate; C_1C_2, cross sections of pencil of rays at P_1P_2. (From *Proc. Camb. Phil. Soc.*, **17**, No. 1, 43; 1913.)

Why did this twenty-two year old student succeed in correctly interpreting the diffraction pattern predicted and discovered by an accomplished theoretician eleven years his senior? Bragg himself modestly attributes it to a "concatenation of fortunate circumstances" but his paper soon convinces you that its success owed more to Bragg's astute powers of penetrating through the apparent complexities of physical mechanisms to their underlying simplicity.

This first paper was quickly followed by another, written in collaboration with his father, on their newly developed X-ray spectrometer, and a third, written by himself alone, solving the structure of common salt and showing how the Laue pictures of several other simple minerals could be indexed. There follows the structure of diamond, solved, as he relates, largely by his father, and the structures of fluorspar, zincblende, iron pyrites, calcite and dolomite solved by himself alone. Finally, on July 16, 1914, he communicated a paper on the structure of metallic copper. In view of this published record and the fact that for most of the relevant period the father was at Leeds and the son at Cambridge, it seems hardly believable that the scientific public tended to attribute most of the credit for these discoveries to his father, sometimes with the undertone that the son had cashed in on the father's success. The son must have suffered a great deal from these thoughtless judgments.

The outbreak of the First World War put an end to further research. Bragg joined the cavalry and was soon detailed to help in the development of sound ranging for the location of enemy batteries. At first he could not separate the report of the gun from the noise of the projectile travelling at supersonic speed. Then he suddenly spotted that the firing of the gun gave rise to a pressure wave, a "rush of air" as he called it, which he was able to detect by its momentary cooling of a hot wire. This simple device made an important contribution to victory.

He resumed his research when, aged twenty-nine, he was appointed Rutherford's successor as professor of physics at Manchester. His early research had replaced the concept of the inorganic molecule by the new one of a three dimensional array of close-packed and electrically compensating ions. The next step was a reformulation, on a structural basis, of the chemistry of the silicates. For example, diopside had been assigned the formula $CaMg(SiO_3)_2$, but B. E. Warren and Bragg discovered that there was no such thing as an SiO_3^{2-} ion. The structural units consisted of SiO_4 tetrahedra as in quartz; these shared corners so that they formed infinite chains bound to their neighbours on all sides by Ca and Mg ions. The varying properties of the many different silicates were found to be a consequence of the ways in which SiO_4 tetrahedra can be linked, sharing corners, edges or faces, and forming long chains as in asbestos, sheets as in mica, or three dimensional networks as in the feldspars, so brilliantly solved by W. H. Taylor. Silicates make up the bulk of the Earth's crust, and Bragg was proud that he and his associates had explained their properties on the basis of their atomic structure. The results of the Manchester school also led Pauling to formulate general rules for the structures of inorganic crystals: atomic arrangements are governed by the ratios of the ionic radii and are stable only if all charges are locally compensated.

When the main structural principles of the silicates had been discovered, Bragg's interest turned to metals. He did not actually solve any metal structure himself, but became absorbed in the X-ray analysis of alloys by A. J. Bradley and others in the Manchester laboratory. His greatest papers of that period are those with E. J. Williams on order–disorder phenomena. For example, in brass at room temperature, copper occupies the corners and zinc the centres of a cubic lattice, but when heated they become more randomly distributed over the two sites until at a critical temperature all long range order ceases abruptly. Why does the approach to disorder suddenly become catastrophic? Bragg and Williams argued that "the decrease in order lessens the forces which tend to keep an atom in its 'right' place, since when disorder is nearly complete the criterion between 'right' and 'wrong' tends to vanish. The effects of increasing thermal agitation and lessening distinction between right and wrong so interact that on approaching a critical temperature the order drops rapidly to zero". Their physical explanation of the catastrophic approach to disorder in alloys later formed the basis for the interpretation of other cooperative phenomena in solids.

I first met Bragg in 1939 at the height of his metallic period, and he put me to work on the X-ray microscope, a neat optical device which he had just invented for the summation of two dimensional Fourier series. He was also keenly interested in my X-ray pictures of haemoglobin, but he did not actually work on the problem until the early fifties when he deduced the correct shape of the haemoglobin molecule from my data. Shortly afterwards he introduced the principle of minimum wavelength which limits the combination of signs in the Fourier transform of a molecule of given size. In the event, the limitations proved insufficient to solve the phase problem in haemoglobin, but the principle later helped D. L. D. Caspar and Rosalind Franklin to solve it in a radial projection of tobacco mosaic virus.

Bragg's last original paper concerned the determination of phase angles by the method of multiple isomorphous replacement with heavy atoms. In monoclinic crystals such as myoglobin or haemoglobin the location of the heavy atoms in the centrosymmetric projection was straightforward, but the determination of their third coordinate, which is not related to any symmetry element in the crystal, posed a difficult problem. Bragg devised an elegant method, based on a principle of physical optics, of deducing these coordinates from the changes in intensity produced by different isomorphous replacements in the same reflexions. As the correct values of the phase angles of several myoglobin reflexions emerged from his calculations he realized that the problem of protein structure, that seemingly hopeless venture which he had backed against all odds for the past eighteen years, could now be solved, and tears of emotion streamed down his face. Bragg's coordinates served as an independent check for those which Kendrew and his collaborators deduced from Patterson syntheses. K. C. Holmes recently used his method to find the heavy atom coordinates in tobacco mosaic virus.

I have tried to summarize Bragg's many other contributions to science in a table which also shows the periods of his different activities in various places (Table 1). The sciences have developed so much faster than the arts. If we think of Bragg as an artist and compare him to, say, Giotto, it is as though he had himself invented three dimensional representation, and then lived through all the styles of European painting from the Renaissance to the present day, to be finally confronted by computer art.

So often men of genius were hellish to live with, but Bragg's creativity was sustained by a happy home life; typically one would find him tending his garden, with Lady Bragg, children and grandchildren somewhere in the background, and before getting down to business he would proudly demonstrate

Table 1 A Chronology of Bragg's Life and Progress

Places and periods of activity

	Important works not mentioned in the text, and books
1921	Intensity of reflexion of X-rays by rock-salt (with R. W. James and C. H. Bosanquet)
1922	Absolute intensities and the determination of structures with several independent parameters (with J. West)
1924	Theory of double defraction in calcite
1924	*X-rays and Crystal Structure* (with W. H. Bragg)
1927	Isomorphous replacement (J. M. Cork)
1929	Fourier projections
1933	*The Crystalline State, A General Survey*
1934	Order–disorder in metals (with E. J. Williams)
1936	Structure factor graphs (with H. Lipson)
1937	*Atomic Structure of Minerals*
1939	X-ray microscope
1940	Structure of cold-worked metal
1942	Bubble model of plastic flow
1945	Fly's eye
1947	Dynamic model of a crystal structure (with J. F. Nye)
1957	Determination of heavy atom parameters in proteins
1965	*Crystal Structure of Minerals* (with G. F. Claringbull)
1971	*The Development of X-ray Analysis*

sity Library SCIENCE COLLEGE. 92 Upper Circular Road CALCUTTA

his latest roses. To the present young generation Bragg was an avuncular figure who showed them that science can be fun. At the Royal Institution he instituted a series of physics lectures for sixth formers, making use of the institution's excellent experimental facilities to bring home the laws of optics, electricity and magnetism. These lectures were attended by 22,000 London school children each year. He also gave a remarkable series of television broadcasts on the properties of matter which brought him popular fame. He was intrigued when the greengrocer woman in Soho told him that he was "the spitting image of a man she saw on the telly last night" and modestly signed the bill for her to keep as a souvenir. Bragg's superb powers of combining simplicity with rigour, his enthusiasm, liveliness and charm of manner, and his beautiful demonstrations all conspired to make him one of the best lecturers on science that ever lived. Yet few realized the formidable intellect that lay behind his genial façade or the decisive and revolutionary contributions to several fields of science for which he had been directly or indirectly responsible. His scientific papers still stand out as models of lucidity and conciseness. They generally contain little mathematics but are based on elegant physical and geometric arguments. His book on *The Crystalline State* once opened a new world to me and remains one of the best elementary introductions to X-ray crystallography.

Most X-ray crystallographers all over the world are "descended" from his or his father's pupils. He regarded them as one family and took the first steps in founding the International Union of Crystallography soon after the end of the Second World War. J. C. Kendrew's and my own early attempts at protein crystallography could not have been sustained throughout the many lean years without his support, and our small group at the Cavendish Laboratory in Cambridge became the nucleus from which the present MRC Laboratory of Molecular Biology later developed. Several other schools, including H. Lipson's at Manchester and W. Cochran's at Edinburgh, are offshoots of his group at the Cavendish. D. C. Phillips's flourishing Molecular Biophysics Laboratory at Oxford stems from the small protein crystallography group which Bragg brought together at the Royal Institution in the 1950s. We all owe him a great debt.

Prosperity and Science as Chicken and Egg

SIR ALEC CAIRNCROSS, President of the British Association at its annual meeting last week, has probably lost a good many friends among professional scientists with his stern declaration that postwar British governments may have been misguided in supposing that investment in scientific research would ensure prosperity and competitiveness with advanced economies such as that of the United States. After all, a great many people have invested their reputations in various versions of this belief, and nobody likes to be told that he has backed the wrong horse, especially when so much time has gone by that he personally may be unable to back another. It is also unfortunately true that much of what has been written in the past, and many government policies on research and development, have been based on the assumption that it might be possible to win extremely quick economic returns from investments in research and development, and to that extent Sir Alec's declaration, reactionary though it may have seemed to some, is entirely well grounded. The expectation that investment in research and development on nuclear power stations in the late fifties would create an internationally dominant nuclear power industry was one of the more conspicuous miscalculations. But it would be a great misfortunate for everybody if Sir Alec Cairncross's complaints that people have expected too much too quickly of scientific research and development should confuse the issue of what connexion there may be in the long run between research and development on the one hand and prosperity and amenity on the other. In particular, it is to be hoped that Lord Rothschild and his helpers, now by all accounts engaged on a comprehensive review of the British government's involvement in research and development, will not use the spirit of Sir Alec's declaration as an excuse for parsimony.

Much of the growth of scientific research in Britain in the last few decades stems from the way in which, in the late forties, a succession of public inquiries drew attention to the great scarcity of skilled manpower in large parts of British industry. But this was also a period in which governments and others hoped that it might be possible in the postwar world to stimulate deliberately the kinds of developments which had given Britain a great reputation for scientific innovation during the Second World War—radar, jet engines and such things as penicillin. Sir Alec Cairncross pointed out last week that Whittle, the man who made the first jet engine, was not a scientist in the ordinary sense but, rather, a man in the more straightforward tradition of the classical inventors. Moreover, the argument goes, jet engines saw the light of day not merely because Whittle was an enthusiast but also because there was an urgent military need of such a development in technology. The implication, of course, is that consumer demand will somehow evoke appropriate technological developments from the community of inventively inclined people, and there is of course some truth in this description of the incentives for invention. How else is it possible to explain the way in which many new developments must be reinvented on half a dozen occasions before they find an economic climate in which full-scale exploitation becomes profitable? From this point of view, the British government's investment in research and development in nuclear power was frustrated not so much by technical difficulties as by the lack of a market. Yet none of this implies that the recognition of the need for some technical development will instantly insure that the necessary inventions are whistled up from thin air, as it were. On the contrary, there is a host of circumstances in which an apparent need for a new technical development has been satisfied not by the local invention of a suitable device in Britain but, rather, by its invention elsewhere. Questions about the relationship between investment in research and development and industrial innovation must be answered by a definition of the economic and social circumstances in which need will stimulate the appropriate developments. The question has been too much ignored.

The most obvious danger, and the most common fault, is to make too sharp the connexion between scientific research and the social or economic need that it must satisfy. This was the British government's fault with nuclear power. Now that advanced communities acknowledge that motor cars can clog up the streets of cities, there is a temptation to spend money on the development of hardware for other kinds of transport such as railways or travelling pavements. Similarly, because exhaust fumes are a nuisance, there is a temptation to spend money on steam engines and electric storage batteries. Yet it may well be that in the long run cities will benefit more from building techniques that make possible and cheap a more complete separation of people and transport, or even from systems analysis that makes transport in the sense of the physical movement of people from one place to another less necessary than at present. It is even possible that the best cities will in future owe less to research on transport as such than to the embodiment in working systems of some of the techniques of electronic communication which have already done much to replace messenger boys by switchboard girls and which still have a long way to go. This is eminently a field in which an attempt to meet a proper and clamant demand for cities that are better organized may encourage inappropriate innovations. Everything depends on whether the vision that inspires the research is of the right breadth, neither too pragmatic nor too abstract.

Strictly industrial developments, electronic computers for example, provoke or should provoke similar considerations. One of the minor scandals of the 1960s is that computer manufacturers made and sold all kinds of equipment with great promises of immediate economic benefit but without means of making sure that the customers would reap the benefits they had been promised. The trouble, in retrospect, is not simply excessive enthusiasm among salesmen but also a failure by computer designers to appreciate the complexity of many of the tasks for which they had commended their machinery. On the face of things, of course, it is paradoxical that there should be few complaints about the way in which computing machinery functions in complicated military innovations such as anti-ballistic missile systems, and endless complaints at the way in which computers function when dealing with practical commercial problems such as the calculation of weekly payrolls, but this should be no surprise; the second situation differs from the first in that it requires computing machinery to be made to play a part in a framework previously designed entirely for people, and to do this for comparable cost. But the persistent failure of computer manufacturers to live up to their promises in the past few years is of course also a definition of a technological need, and there is no doubt of handsome profits for whichever manufacturer of computers finds himself able to make machinery that functions as it is said in the brochure to function.

In countries such as Britain, there are particular economic and social needs which cry out to be satisfied. What is to be done about shipbuilding? Does Britain, either separately or as a part of the European Community, have a future as a manufacturer of aircraft or of the electronic systems with which modern aircraft are filled? Is there some way of making the automobile industry competitive in circumstances in which it seems all too probable that manufacturers on the mainland have already won the race, both in technical quality and in the cost of production? And if sober consideration does suggest that traditional industries will have very little to contribute to British success in the European economic competition for the few decades during which the European Community will be a club of economic competitors, not a federation of like-minded states, what new industries will give the British economy grist for its mill in the years ahead? It is impossible to see how any of these questions could be answered without an intellectually strong scientific community in Britain able to provide the men and women capable of solving not merely the problems which exist but those which have not yet emerged.

Quite apart from over-optimism about the probable connexion between research and prosperity, the past few decades have seen in Britain the reflexion in science policy of some of the problems which have confused international relations as a whole—the tendency to believe that even small countries such as Britain could remain creative and successful in all possible industrial fields, the tendency to suppose that native wit and intelligence would be a match for the systematic deployment of imagination and skill, backed by money, in countries such as the United States, and the suspicion that the inherent virtues of British manufactures would somehow make unnecessary attention to such skills as marketing, still regarded in Britain as techniques appropriate to second-rate commodities. In the past few years, as luck will have it, British society seems to have acknowledged that these principles are now untenable. One of the dangers of too literal a reading of what Sir Alec Cairncross had to say last week is that the tendency towards braggadocio in British science policy, which he has mistaken for a more pedestrian if less reprehensible wish to turn research into gold, may now be replaced by the equivalent in research policy of what the Little Englanders would do in politics. In short, there is a danger, which the present government so far has given no sign of acknowledging, that public policies on the scale and balance of research and development will in future be guided by the most pragmatic and expedient calculations.

This is why the British government, and Sir Alec Cairncross as well, should read carefully the speech on Monday this week in which Sir Brian Flowers, chairman of the Science Research Council, made the first official attempt so far to anticipate the effects on British policy for research and development of entry into the European Community. Over the years, British governments have taken an entirely misguided view of what the European relationship entails. A decade ago, when the first attempt was being made to win entry into the Common Market, people such as the then Minister of Aviation, Mr Peter (now Lord) Thorneycroft, hoped that it might be possible to make the process easier by offering the rocket Blue Streak as a basis for the development of the European Launcher Development Organization. By now, there is plenty of evidence that Mr Thorneycroft's calculation was mistaken. In Mr Harold Wilson's time, the British government offered an even more ambitious version of the same prospectus, proclaiming the advantages of what it called a technological community in Europe, but what was intended was simply a more grandiose system in which European countries would collaborate with each other on a multitude of projects, no doubt hoping against hope somehow to resolve the perennial problems of how best to share out contracts and kudos fairly among participants and non-participants.

The merit of what Sir Brian Flowers has to say is that it recognizes the importance (see *Nature*, **230**, 198; and **231**, 3; 1971) that European collaboration should allow participants to concentrate on the things that they do best without fearing that competitors will in the process steal a march on them. Although most discussions of British membership of the European Community have been based on the assumption that the six present members, and the ten that there will be if the new applicants eventually join, are a group of nations bound together by artificial rules in such a way as to make economic competition more wounding than it would otherwise be, the truth is that the European pattern is one that may enormously simplify the European economy. The fact that tariff barriers disappear implies that once chauvinism has been eroded by the passage of time, customers will buy the cheapest products without concern for where they come from, and industries will therefore find themselves concentrating on a few manufacturing plants, not a random scattering throughout Europe. But in this state of affairs, it will be important that there should be opportunities for skilled technical people to move freely to where their ingenuity can best be employed (which is also one of the conditions of the Treaty of Rome) by which time it will be apparent that if British industry is unable to use the skills of its graduates in science and technology, other countries will be eager to do so. But from this it follows, as night from day, that attempts will have to be made to coordinate the policies on research and development which the separate governments pursue. In the long run, the result is bound to be an integration of the university systems as well as of policies for research and development. The British government is lucky that Sir Brian Flowers has now pointed out the need for moving in this direction. It is unfortunate that Sir Alec Cairncross had nothing to say on the subject last week.

Where Real Trouble Lies

In the past several months, all kinds of fears have been expressed about the damage that might be done by pollution of various kinds to species of animals which are either of economic importance or of some other value to society at large. By now, for example, it is known that DDT and other organochlorine pesticides can damage the reproductive capacity of birds, particularly falcons and eagles. Similarly, there have been fears that pesticides and other chemicals in the sea may cause irreparable damage to breeding stocks of fish or other sea animals. It is therefore ironical but important that signs are now rapidly accumulating to show that the most serious and rapidly growing threat to the survival of these species lies not in any form of pollution but in the activities, sometimes illegal, of people armed with nothing more unfamiliar than guns and trawling nets.

The case of the American eagle is already something of a scandal. Over the years, the populations of the bald eagle and the golden eagle have steadily declined to 2,000 and 8,000 respectively and, because both birds are protected by federal legislation, it has been assumed that the decline in their populations is to be attributed to the hostile influences of the contemporary environment, DDT and all. But now it turns out that farmers in states such as Wyoming, anxious to protect flocks of sheep and other livestock against predators, have been hiring helicopters so as to destroy eagles in flight. One estimate is that close on a thousand eagles have been destroyed by these techniques in Wyoming in the past year, and it is clear that others have been killed by poisoned bait of various kinds. On the face of things, at least, it looks very much as if the illegal operations of the farmers are in themselves sufficient to account for the decline in the populations of the eagles, and that they are sufficient to jeopardize the future of the two species. Because there are bound to be serious limits to the efficiency with which the law can be enforced, is there not a strong case for asking that some of the ecologists who worry about the effects of pesticides on the breeding stocks of eagles in North America should turn their attention to such a close understanding of the habits of these splendid creatures that means might be evolved for keeping them out of reach of their most serious enemies, the farmers of the north-west?

The case of vertebrates in the North Atlantic is potentially much more serious. It is already well established that at least two species of whale have been exterminated as a result of hunting in Antarctic waters, and others are in danger (see *Nature*, **232**, 80; 1971). There is now a serious danger that species of commercial fish may be exposed to insupportable pressure from fishing vessels. It is already well documented that the catch of herring in the North Sea and around the British Isles has declined steadily since the Second World War, and this is one of the reasons why the British government is sensitive about the limits preserved for national fishing in coastal waters, due to be negotiated in Brussels this week with the members of the European Community. But it is also becoming harder for fishing vessels to keep up their productivity in catches of cod and haddock, two of the principal catches in the North Atlantic. Figures recently made available by the Fisheries Research Board of Canada (ref. Technical Report 260) illustrate how sharp has been the decline of the population on what is called the Scotia Bank, the shallow region of the continental shelf east and south of Nova Scotia. By means of comprehensive samples in the region, it has been possible to show that for both species, the present rates of exploitation are comparable with or even exceed the maximum sustainable yield of the two species. But there is at present no limit to the intensity of fishing in regions such as this; instead, there is a constant incentive to travel further afield in search of fish. Although not nearly enough is known of the population dynamics of cod and haddock, there is at least a strong danger that over-fishing could bring about a marked reduction of the stocks of fish available within a decade.

One obvious moral is that some attempt should be made to set up international controls of the intensity of fishing in the North Atlantic. If the snail's pace at which similar attempts to restrict the sovereignty of nations and the independence of fishermen is any guide, a decade leaves hardly any time for manoeuvre. The second important lesson is that those who fear the way in which pollution of various kinds may damage marine life should acknowledge that whatever the rightness of their case, there are still more urgent problems to be tackled.

---

100 Years Ago

The Aurora

I HAVE just read Mr. Wilson's interesting paper entitled "Some Speculations on the Auroras," published in your periodical for September 7. In the *Philosophical Magazine* for July 1870 I made a suggestion as to the origin of auroras similar to that just published by Mr. Wilson.

The periodicity in auroral displays noticed by Mr. Wilson had not attracted my attention. It would doubtless, if it were well established, be confirmatory of the views independently put forward by Mr. Wilson and myself. A. S. DAVIS

Meteor

ON Saturday, September 2, at 8.14 or 8.15 P.M., I saw a fine meteor under very favourable circumstances. I was standing with several friends at the door of Mr. W. F. Moore's house at Croakbourne, in the Isle of Man, and we were looking up at the western sky at the moment when the meteor came. It started between, I think, γ and π Herculis (it was too cloudy to see those stars), descended nearly vertically, passing through Corona Borealis, and vanished a little below ζ Bootis, at about 15° above the horizon. It moved slowly but continuously, taking from two to three seconds in travelling over 45°. It broke into three, which followed one another, connected and followed by a luminous train which was visible for about one second. The first part of the three was brilliant white, and was estimated by Mr. A. W. Moore and myself independently as equal in size to $\frac{1}{8}$th of the moon's surface. It was very brilliant, being mistaken by the Rev. John Howard, who was looking in another direction, for a flash of lightning. The two latter globes were blue.

OLD WORLD

BRITISH ASSOCIATION

Cross Roads Again

from our Special Correspondent

Swansea, September 8

THE 135th annual meeting of the British Association, now finished, has been more than usually a demonstration of how much the association has to offer and a source of anxiety that it might not be able to continue. The scientific programme has been imaginative if unspectacular. The association has also gone a long way to meet the criticism that it has done too little in the past to provide a forum for the discussion of important public issues in the management and exploitation of science. But a cloud, now very much bigger than a man's hand, continually hangs over the association's future. It remains to be seen whether the decisions taken this week will provide an administrative framework in which the association will be able to survive.

The mood of the annual meeting, a cautious blend of enthusiasm and scepticism, was in part determined by the opening address of the president, Sir Alec Cairncross, who argued that economic history contains very little evidence to suggest that "the process of innovation owed much directly, even if it owed a great deal indirectly, to advances in scientific knowledge". The result, he said, is that those "who put their faith in science as a means of our economic salvation exaggerate the part played by the body of formulated knowledge in the generation of technological change". He went on to say that it is consumer demand—the interests of governments as well as of individuals—and not advances in scientific knowledge that "gives innovation its motive-force", and that in the moulding of innovation by consumer demand, what matters most is the way in which industrial management exploits the potentiality of techniques.

The moral which Sir Alec Cairncross drew from this analysis is that there is no correlation between expenditure on research and development and the rate of economic growth. The suspicion that there must be has, in Britain, moulded government policy towards innovation in such a way that "the problem was misconceived, the strategy mistaken, the tactics unsatisfactory . . .". For the British and for other governments, the social climate is also an important determinant of the pace of innovation. Britain has been unlucky in this respect. But for all governments, according to Sir Alec, innovation "comes far more from below than above". Governments may be able to cajole but they cannot direct.

Sir Alec's declaration has drawn a number of opponents in the past week. At a public discussion on Monday evening, Sir Brian Flowers, the chairman of the Science Research Council, said that he could have written a similar address to the Royal Institute of Economics, replacing the word "science" by "economics". Sir Alec himself is anxious to insist on the distinction between science and technology, so that in that sense his argument is not relevant to all the things that British governments have done in the past few years to foster innovation in industry.

One of the ingredients missing from Sir Alec's address was a sense of what might happen or should happen in the planning of government policy. From a quite different point of view Sir Brian Flowers spelled out on Monday some of the steps which in his view must be taken to foster the development of science within the European Community, with luck enlarged by the accession of Britain and the other applicants. (The full text of this address will appear in *Nature* in the near future.) On the creation of common institutions he asked that innovators should insist "the science must be good science" and the purpose of the institution must be clear. But the initiative for creating a new organization must come from scientists and there must be good reasons for thinking that international collaboration is essential. With these conditions satisfied, Sir Brian considers that there are great benefits to be won in the development of the European economy, especially if ways can be found of encouraging the nations of Europe to "give up the idea of alternative and purely national ventures".

Elsewhere, various sections of the association have sought to lay down the law on what should be done to brighten or to make more liberal the education of science graduates at British universities—these days, it seems, the advocates of liberal courses are the only ones who dare to speak in public. Several of the meetings in the past week have been designed to draw attention to social problems inherent in scientific developments of all kinds, and there has been a particularly successful discussion, led by Professor R. R. Porter, of the social problems occasioned by medical research. The same question was argued over at a discussion to which members of the general public were invited—an innovation for the British Association.

Controversy about the place of science in the modern world has sprung up at several sessions, sometimes by accident and sometimes by design. Nobody is in a position to count heads and thus identify the winner. On balance, however, this year's meeting has been distinguished by much more open discussion of the social antecedents of science, which is why the statement issued by the British Society for Social Responsibility in Science that "a few tame symposia on environmental things, a few public lectures on the ethical problem of this or that are not a real response to this crisis" has fallen a little flat.

This "crisis" is whether the British Association will somehow manage to survive. The association seems to have gained very little from the year long study by the Committee of Review (see *Nature*, **231**, 412; 1971). The financial position is now even more desperate.

Letter from Rothschild

SIR,—In your leading article on August 20 you referred to "inexcusable delays" on the part of the Government in reaching important decisions. You cited the study of certain aspects of Government research and development.

The Central Policy Review Staff was asked by the Government at the end of March to report on this subject by October. Given the complexity of the issues involved, to which your article testifies, six months is surely not too long for a study of the organization and management required for the annual expenditure of £650 million of public funds. This study has obviously entailed "the ample discussion with interested parties" which you imply the Government has been neglecting.

You also argue that in the management of the Government's policy on research and development, "the machinery that exists is a hindrance, not a help". It is precisely this question of the machinery which the CPRS has been studying.

Yours faithfully,
LORD ROTHSCHILD

11 Herschel Road,
Cambridge

It is good to know that the Rothschild inquiry is well on with its work, but must everything wait until its report has been digested? And will the Dainton report on the Research Councils be published?

EDITOR.

RADIO TELESCOPES

Jodrell Bank in Wales

by our Astronomy Correspondent

THE Science Research Council has earmarked £250,000 for a detailed design study of the telescope which the Nuffield Radio Astronomy Laboratory at Jodrell Bank, and in particular the laboratory's director, Sir Bernard Lovell, have looked forward to building for years. But it is clear that Sir Bernard's original aspirations have had what—instead of the 400-foot dish the Jodrell Bank group had hoped to build, the design study is for a telescope with an aperture of 375 feet. Steel prices have also made it economic to replace much of the steel in the original design by concrete.

Nevertheless, the Mark VA, as it will be called to distinguish it from the original design, will be the largest fully steerable radio telescope. Its diameter will be 47 feet greater than the current holder of the record, the telescope that is at present being brought into operation at Effelsberg, West Germany, by the University of Bonn.

But the design philosophy of the new Jodrell Bank telescope will be radically different from that of the Bonn telescope. The Bonn telescope has a light structure which is designed to distort under the forces of gravity and wind loading in such a way that the surface always remains a paraboloid to a sufficient accuracy for observations down to wavelengths of a few centimetres. In the design for the Mark VA the effects of wind are to be reduced by using a heavier structure, and the position of the reflecting membrane will be adjusted during operation by means of screw jacks attached to the backing structure to allow for gravity distortions at different elevations.

The steel backing structure which will carry the membrane of the Mark VA will pivot in elevation on bearings supported by a beam which in turn will be supported by a concrete turntable. It is hoped that the telescope will be operable down to three centimetres.

Last week's announcement by the Science Research Council should put European radio astronomers at a further advantage compared with radio astronomers in the United States, where the lack of new radio telescope projects is widely lamented. In Europe, on the other hand, significant new telescopes have recently begun operation at Westerbork in Holland and at Effelsberg, and a three-mile interferometer is under construction for Sir Martin Ryle's group at Cambridge. But it will clearly be past the middle of the decade before the Mark VA could be completed—it will be a year before the design study will have progressed far enough for tenders to be invited, and it is expected that the telescope will take three or four years to build, at a cost that is likely to be more than £4 million. Consulting engineers for the Mark VA will once again be Husband and Company, who were responsible for the 250-foot telescope at Jodrell Bank.

Although most radio astronomers will undoubtably welcome last week's news, some astronomers have argued that the wealth of instruments becoming available to radio astronomers in Europe makes the construction of a radio telescope able to operate down to millimetre wavelengths more urgent than the Mark VA (see *Nature*, **227**, 107; 1970). Such a telescope would primarily be valuable for work on interstellar molecules which have characteristic lines at centimetre and millimetre wavelengths, and would allow European astronomers to participate in a field which up to now has been dominated by the Americans. It is understood, however, that such a telescope may be under consideration by the Science Research Council, although for reasons of atmospheric transparency it could not be situated in Britain.

The site chosen for the Mark VA is at the village of Meifod in Montgomeryshire, fifty miles from Jodrell Bank, and to a considerable extent the telescope will be controlled automatically from Jodrell Bank. Land was bought at Meifod three years ago for the laboratory, with a view to Meifod being the site of the Mark V telescope, although planning permission for the dish has not yet been applied for. Although the people of Meifod are reported as being in favour of the plan, Meifod also happens to be the headquarters of the Council for the Protection of Rural Wales, which has made available the following statement: "The telescope will be completely out of scale with the Meifod valley, a countryside of small and intimate detail and exceptional beauty. The nearest hill to the site rises little more than the diameter of the dish.

"Sir Bernard has said recently that the whole of Britain was searched for a suitable site. We understand that only scientific criteria were taken into consideration in these searches and the appearance of the landscape was ignored. No consultations were held with the Countryside Commission. Local opinion is in favour of the telescope but it is now realized that our countryside is a matter of concern for everyone in Britain. Local opinion believes that Meifod will be 'put on the map'. However, the benefits may be illusory since employment will be minimal once the site is built. Sir Bernard has told us that tourism will not be encouraged because of electrical interference and tourist facilities have already been provided at Jodrell Bank. The danger of electrical interference will also inhibit the natural development of the area within range of the site."

POLLUTION

Canberra Conference

from a Correspondent

Some of the guidelines for the long awaited United Nations Conference on the Human Environment to be held in June 1972 in Stockholm became clearer during a thirteen nation meeting of the UNESCO advisory committee held in Canberra on August 23–27. The recommendations of the committee on Natural Resources were couched in general terms but they give some idea of the directions which UNESCO would like the Stockholm conference to take.

The committee proposed that interdisciplinary projects should be emphasized including both social and natural sciences and that priority should also be given to continuing and expanding those projects begun under the aegis of the International Biological Programme which have proved to be successful. The committee also favoured an early start to some projects which are likely to be productive in order to get the forthcoming "Man and the Biosphere" programme, that is being sponsored by UNESCO, firmly established. Also it recommended that projects should "concentrate on the study of dynamic rather than static phenomena".

The committee further recommended that a set of ecological guidelines for development projects should be prepared to encourage planners of major works, such as large dams, to include ecological considerations in their planning. The director of UNESCO's Natural Resources Division, Dr Michel Batisse, said that he hoped that UNESCO would publish some definitive guidelines after the Stockholm conference. The administration of Man and the Biosphere was criticized by the advisory committee, as was the administration of the International Geological Correlation Programme (IGCP). The committee recommended that the IGCP administration should come under a single coordinating body whose members would be appointed jointly by the Director-General of UNESCO and the President of the International Union of Geological Sciences (IUGS). The IGCP is a joint project of UNESCO and IUGS that is planned to begin in 1973. Its aims are to correlate geological knowledge of different areas—partly in the hope of encouraging new mineral finds. These recommendations will be put to an inter-governmental conference to continue preparations for the IGCP which will be held in Paris on October 19–29.

Dr Michel Batisse said that Man and the Biosphere was receiving strong support from developing countries, communist countries and most western nations but that the United States appeared only moderately enthusiastic with Britain also treating the programme very coolly. Professor J. N. Black of the Forestry and Natural Resources Department, Edinburgh University, was elected chairman of the advisory committee, which possibly signifies an increase in Britain's support.

SRC Members

THE Secretary of State for Education and Science, Mrs Margaret Thatcher, has this week appointed two new members to the Science Research Council to replace Professor Sir Ronald Nyholm and Professor P. A. Sheppard, who have retired from the council. They are Professor H. Elliot of Imperial College, London University, and Professor R. Mason of the University of Sussex. The composition of the council from October 1 will then be: Professor Sir Brian Flowers (chairman), Dr A. H. Chilver, Dr D. S. Davies, Dr E. Eastwood, Professor H. Elliot, Professor H. Ford, Professor J. C. Gunn, Professor F. Hoyle, Professor H. L. Kronberg, Professor R. Mason, Professor P. T. Matthews, Dr J. W. Menter, Professor E. W. J. Mitchell, Mr D. L. Nicolson, Dr E. J. Richards and Professor M. M. Swann.

NUCLEAR REACTORS

All Set at Dounreay

ALTHOUGH the construction of the British prototype fast breeder reactor is running about eighteen months behind schedule, it is still ahead of similar projects in other countries. The prototype is being built by the Nuclear Power Group at the United Kingdom Atomic Energy Authority Experimental Reactor Establishment at Dounreay in the North of Scotland, and should be completed at the end of this year.

The original plan was that the reactor system should deliver power to the North of Scotland Hydroelectric Board during the first half of this year, but because of trouble with the construction of the roof of the reactor vessel, commissioning is now expected to take place early in 1972 with the first output of elecricity at the end of the year. By contrast with the smaller Dounreay fast reactor which first went critical twelve years ago and has been producing about 14 megawatts (MW) of electricity as well as providing a valuable irradiation facility, the prototype fast reactor (which has cost about £38 million) will generate at least 250 MW and earn about £4 million a year from electricity sales. A further £2 million a year will probably accrue from rental of irradiation space in the core.

The Dounreay prototype fast reactor represents an important link between the small experimental fast breeder and the reactors needed for a new generation of nuclear power stations. The Central Electricity Generating Board is seriously considering the feasibility of fast breeder reactor stations and proved commercial systems could also be sold abroad provided that the designs are not so geared to the requirements of the Central Electricity Generating Board that they are unattractive to other potential customers (a situation that may account in part for the poor response to the British advanced gas-cooled reactors). Discussions between the Atomic Energy Authority and the Central Electricity Generating Board have led to a proposal that a 1,300 MW fast reactor power station should be started in 1974. This would cost about £130 million, but any decision to go ahead with such a project cannot be taken until the satisfactory operation of the Dounreay prototype fast reactor is assured and the thorny problem of siting fast reactors near centres of population is at least partially resolved. The Central Electricity Generating Board would certainly not be happy with a remote station because of the high costs of electricity transmission. A definite choice of site for the first commercial fast reactor will, however, have to be made during 1972 if the rather ambitious 1974 deadline is to be met.

In spite of the interruptions in the Dounreay prototype reactor programme, only the Russian 350 MW prototype reactor at Shevchenko is being built on a comparable timescale; a full-size Russian system is, however, unlikely to be a serious commercial competitor in the West. A French 250 MW prototype reactor project is under way at Marcoule, but the core is not expected to go critical before 1973. In the United States General Electric and Westinghouse have designed a "demonstration" fast breeder reactor but construction has not yet started.

Britain is also involved in two collaborative fast reactor ventures in Europe. In 1969, the Nuclear Power Group joined representatives of eight European countries in a project to investigate gas cooled fast reactors (as opposed to the sodium cooled fast reactors such as the Dounreay prototype); the group is also involved with Kraftwerk Union (through its associated company Interatom), Belgonucleaire and Neratoom in an agreement to market fast reactors eventually on a worldwide basis. Interatom, Belgonucleaire and Neratoom are at present working on the design of a 300 MW fast reactor to be built in West Germany.

The Dounreay Experimental Reactor Establishment. The prototype fast reactor is in the right background, and the older Dounreay fast reactor is in the left foreground.

SPACE SCIENCE

Probing Mars

from our Soviet Correspondent

THE Soviet Mars-2 and Mars-3 probes, launched on May 19 and 28, 1971, and now half-way through their six-month voyage to their target, not only carry experiments for the study of Mars and circum-Martian space, they also have on board a number of experiments intended to operate during the voyage itself. These are intended to measure magnetic field strength, the flux of charged particles and study the solar wind.

The solar wind experiment, which appears to be the most important to the Soviet space programme at this stage, is designed to determine the velocity, temperature and composition of the principal components of the solar wind and the variation of these parameters with time and distance. It includes an ion-electron spectrometer unit, capable of measuring the spectral distribution of the particles from 30 eV to 10 keV. This unit consists of eight individual spectrometers, each consisting of an electrostatic analyser, a high-gain electron channel multiplier (the first to be produced in the Soviet Union), sampling schemes and a signal recording device.

The first results from the solar wind experiment are now being analysed, and are providing good evidence of the satisfactory design of the unit. Some typical data so far obtained, for the first 10 days of the flight of Mars-3, are that velocity of the solar wind fluctuated between 300 and 600 km s^{-1}, relative content of alpha-particles varied from 5 to 10 per cent. The temperature of the solar wind particles and the considerable velocity gradients recorded are the subject of further and more detailed study.

The time-gap between the launching of the two probes and the availability of readings from other Soviet projects makes it possible to estimate which fluctuations are due to variation along the trajectory and which are due to variation in time. The solar wind data obtained from Lunokhod-1 and from the Earth-orbiting Kosmos satellites are providing reference data against which the Mars-2 and 3 data may be more clearly evaluated.

ENVIRONMENT

A-level Development

THE third attempt in recent years to develop an A-level syllabus in environmental studies was launched last week by a party of school teachers from Hertfordshire (*Environmental Studies—The Construction of an A-Level Syllabus*; National Foundation for Educational Research in England and Wales). The other two attempts, in 1968–69 and 1970, were unsuccessful but the present proposal has been constructed in greater depth. The Hertfordshire County Adviser for Environmental Studies, Mr S. McB. Carson, said this week that he was optimistic that the present submission would be accepted by the examination boards and the Schools Council.

There are twenty-two schools and two colleges in Hertfordshire that are planning to start teaching the new syllabus in September 1972 if approval is granted by then, and there are four examination boards that have already been approached with a view to instituting the syllabus. These are the University Entrance and Schools Examination Council of London University, the Associated Examining Board, the Cambridge University Local Examination Syndicate and the Oxford Delegacy of Local Examinations. With the exception of the Associated Board which is not sympathetic to the new syllabus, the other boards are considering the proposal. Before the syllabus can be instituted, however, the boards must submit it to the Schools Council for approval. If approval is granted it is unlikely that more than one examination board will eventually offer the examination and arrangements will probably be made, as is currently done in other subjects for that one board to offer the examination to the schools attached to the seven other boards.

The development of an A-level course in environmental studies is a natural consequence of the O-level and CSE examinations in similar subjects that are already recognized by several examination boards. A problem in instituting the syllabus at A-level will be to find qualified teachers. Mr Carson said this week that the plan in Hertfordshire is to have the teaching done by biologists and geographers, or by specialist environment teachers—either those who are now involved in teaching the O-level subjects or by graduates of one of the several universities that now offer courses in environmental studies. The overlap of the new syllabus with other topics already being taught in schools is not a problem, according to Mr Carson, and of the fifteen university faculties that have in principle approved of the subject as an entry requirement, only one expressed reservations about a candidate offering both environmental studies and biology.

One of the arguments in favour of the new syllabus, says Mr Carson, is the increasing awareness of today's sixth-formers about ecological problems. Unlike most A-level syllabuses, A-level environmental studies will be as relevant as anybody could wish. Another potential advantage of the syllabus is that it offers career opportunities at non-degree level in teacher training and in Town and Country Planning.

BIOMEDICAL RESEARCH

Science Looks Forward ?

by our Special Correspondent

"Too plainly we are—in common with the whole of humanity—confronted with the question of where (the development of biology and medicine) leads." This was the reasoning which led Hoffman-La-Roche to celebrate their 75th anniversary by holding a symposium, "The Challenge of Life", in Basle last week. The aim of the symposium was outlined by Dr Alfred Pletscher (Hoffman-La-Roche) as "to define more clearly the problems created by biomedical progress and to find, if possible, essential facts or clues for their solution". Although the illustrious assembly of speakers, which included not only biologists but also sociologists, philosophers and even theologians, was, of course, unable to provide definitive answers to this ambitious question, this proved to be one of the very few conferences where a consensus of opinion emerged to pinpoint with some clarity the essential problems which need to be resolved.

Some fascinating clashes of temperament dominated the symposium, in particular the conflict between the idealism of Dr Philip Handler (President, US National Academy of Sciences) and the pragmatism of Solly Lord Zuckerman (former Chief Scientific Advisor to the British Government). Whilst Professor Joshua Lederberg (Stanford University) and Professor Arnold Burgeon (Director, National Institute for Medical Research, Mill Hill) strongly urged that it is essential for scientists to communicate with the public and to reverse the alienation which many laymen now feel from science, Professor Niels Jerne (Director, Basle Institute for Immunology) maintained that it is impossible and, indeed, perhaps undesirable, for scientists to popularize their work.

Any curtailment of basic research would be tantamount to the book burning of the Nazis, said Dr Handler and Professor René Konig (University of Cologne), whilst others, in particular Professor Bernard Barber (Columbia University), were adamant that, to some extent at least, the sociologist, as a representative of public opinion, should be allowed to sit in judgment on the scientist. And Professor Margaret Mead (American Museum of Natural History) wished that the scientist would listen to the warnings that the social sciences can provide of reactions such as the backlash to science.

The consensus of opinion was with Professor Salvador Luria (Massachusetts Institute of Technology) that the critical point for control is not the direction of basic research but its technological development. And as Lord Todd (University of Cambridge) said, the problem of overpopulation loomed large over the entire proceedings. The right of the individual to expect medical science to maintain him in good health was defended by doctors, including Professor Burgeon and Max Lord Rosenheim (President, Royal College of Physicians of London), but the meaning of this was challenged by Professor Jeanne Hersch (University of Geneva). One of the main talking points was Lord Zuckerman's insistence that governments simply lack the resources to keep up with the demands for expensive treatments, and that medical science is aggravating this problem by devising more of these treatments.

A more detailed account of these discussions will appear in *Nature* next week.

GRADUATE EMPLOYMENT

A Question of Degree

CONCERN over graduate employment prospects and over the efficiency and effectiveness of the service that appointments boards provide marked the meeting of the Standing Conference of University Appointments Services (SCUAS) held in Cambridge last week. The conference, which meets every two years, was attended by 150 appointments officers and 70 guests, and took as its theme "Appointments Services in a Changing World".

Professor R. V. Jones, Professor of Natural Philosophy at the University of Aberdeen, outlined some of these changes in his opening address to the conference. After tracing the history of university education, Professor Jones suggested that the increase in the number of graduates had not been matched by an increase in quality. He went on to say that this factor combined with the present overproduction of specialist scientists will result in increasing numbers of science graduates following non-specialist employment.

To adapt to this situation science courses may have to be altered to produce more generally employable graduates. Professor Jones argued for a common course in the early stages of university education to prepare three types of graduates—those who would go on to be professional scientists, including teachers, those who would be professionally employed but not in the fields of research or design, and those who would almost immediately move outside science. He also suggested that demand would again equate to supply in the mid-1980s.

But, for the present, opinions varied as to the seriousness of the situation, Mr H. B. Putt, the retiring chairman of SCUAS, thought it possible that by the end of the year the situation "will be less disturbing than we had at one time feared". Mr Bernard Holloway, of the Manchester University Board, SCUAS's very own Job's comforter, felt otherwise. He predicted that by the end of the year the situation would be "worse than our worst fears", that 1972 would be at least as bad, and that 1971 was "the first of the seven lean years".

The duty of appointments officers, he said, was to be pessimistic, so that everyone became aware of the problems facing graduates. Mr Tom Snow, of the Oxford Board, while admitting that there are more graduates than traditional graduate jobs, denied that the situation was doomladen, and argued that "the function of education is not to fill gaps in the economic system". The impression must not be produced that higher education is a waste of money. Graduates, he felt, were still a very saleable product. He pointed out that by 1981, 30 per cent of men and 25 per cent of all eighteen-year-olds will be receiving higher education, and that the appointments boards should draw attention to the need they are, and will be, filling.

But it became clear from the conference that, saleable or not, to accommodate the growth in graduate numbers in the next ten years there will have to be a number of basic changes in attitude by students, schools, employers, unions and academics. All will have to become more flexible. University education will have, in the words of Mr Neil Scott of Nottingham University Board, to become an "education for citizenship", and much less a passport for a job. Graduates, particularly those who are not first-class material in either research or industrial terms, will have to be prepared to start at the bottom of their chosen ladder, and spend some years training. Students will have to realize this before they go to university, or, as Mr Holloway pointed out, graduates with unfulfilled expectations may produce a lot of resentment in society.

The expectation of what university has to offer will have to change at school level. This means alerting headmasters, of whom there were only two at the conference, as well as career teachers to the new realities. Academics too may have to be more flexible and provide broader based courses, and the conference will suggest to appropriate bodies that when new courses are planned appointments boards might have something to say. Employers will also have to accept that many jobs now filled by A-level entrants will in future be filled by graduates. Some employers are well aware of this—the GPO's traditional A-level white collar entry is now two-thirds filled by graduates.

Mr W. P. Kirkman, President of SCUAS, and Secretary of Cambridge University Appointments Board. "SCUAS", he says, "must be very well aware of changes, and move to meet them, but beware of rushing up any side track that comes along".

In fields where graduates have rarely if ever penetrated before there will have to be radical changes. Pay and promotion structures will have to be altered to allow graduate entry—at present their degree can put graduates automatically on to too high a pay and promotion scale for the employer to be able to afford to train them. Potential problems with unions who will object to the intrusion of graduates in their ranks will have to be ironed out.

But if the conference was aware of the limitations of other organizations, it was also aware of its own. The need for a central service unit which would provide badly needed centralized organization and prevent pointless duplication of work was reiterated, and it is likely that some such organization will soon be established. The American placement offices have had a central organization for the past fifteen years.

The use of a computer matching service, to cut out much of the routine paperwork, is being considered. This would allow the student to find early in the year what jobs are available in the fields in which he is interested. The system requires comparatively little personal information, and the National Union of Students, subject to certain safeguards, is cautiously enthusiastic.

A computer would allow more time for actual counselling, to help find graduates the kind of job suited to their talents, and, as Miss Audrey Newsome of Keele University pointed out, it is just that that the appointments boards must provide if they are not to become irrelevant to student needs. Miss Newsome also pointed out that appointments officers, although they are often experienced, are essentially an amateur body, and she called for training courses in counselling. Students, she said, must be met and helped before they come to feel that appointments boards are irrelevant.

Overall the conference was active without being pushed into panic by one particularly bad year, and they established a number of long-term studies to continue to examine their role. Their main problem is that while they have a close and constructive relationship with employers, particularly through the 300 members of the Standing Conference of Employers of Graduates, and, on the whole a good relationship with students, the appointments boards relationship with the universities, although improving is by no means uniformly good. They feel that now universities might listen more to what they have to say, and possibly spend more on them. The country spends about £80 getting a student to university, £3,500 educating him, and about £22 finding him a job. That balance is going to have to change if appointments boards are to provide the graduate with the service he needs.

NEW WORLD

AEC Causes Anger and Delight

by our Washington Correspondent

ACCUSED by the Court of Appeals of foot-dragging in its implementation of the National Environmental Policy Act, and of making a mockery of the act's intentions, the Atomic Energy Commission has reacted with a swiftness and boldness that suggest that the court hit a particularly sensitive spot. Little more than a month after being told by the court to take another look at its licensing policies, the AEC has come up with a new set of regulations which include every environmental safeguard that the court demanded, and which threaten to shut down five plants that are already operating and to halt construction on forty-six others while their environmental effects are reviewed. The new regulations also threaten to land the AEC in a flood of court actions brought by angry electricity companies who will have to foot the bill for costly delays and who face the prospect of adding expensive modifications to their plants to reduce environmental damage. When James R. Schlesinger, who took over as chairman of the Atomic Energy Commission on August 16, promised to be sympathetic to the demands of environmentalists, few expected him to demonstrate his sympathies quite so quickly or so dramatically.

The new regulations were made in response to a ruling of the US Court of Appeals which, on July 23, took the AEC to task for not considering environmental issues as a matter of course when an application to construct or operate a nuclear plant is given a public hearing; for excluding environmental issues from being considered in any public hearing announced before March 4, 1971 (fourteen months after the National Environmental Policy Act came into force); for failing to evaluate and balance certain environmental factors by abdicating its responsibilities to other agencies, and for allowing electricity companies to carry on construction of plants which have not been reviewed under the procedure laid down by the National Environmental Policy Act (NEPA).

It took the AEC more than eleven months after NEPA came into force to draw up regulations to comply with the act's intentions, but only one month to design new regulations to comply with the court's ruling. Some indication of the haste with which the AEC moved to meet the objections of its environmentalist critics can be gauged by the fact that when the new regulations were announced last week, the commission was unable to say how many plants at present being constructed, or which have recently been given operating licences, would be affected by each section of the new regulations. Hurried discussions at the AEC's headquarters, however, produced a list some seven hours after the regulations were made public.

AEC's "Mockery"

THE AEC's new environmental regulations sprung from a decision of the US appeals court on July 23, 1971, in which a group of environmentalist organizations accused the AEC of paying insufficient attention to the National Environmental Policy Act, particularly in regard to construction of a nuclear power plant on the Chesapeake Bay in Maryland. The following extracts are taken from the opinions of the appeals court:

The environmentalists charged the AEC with not submitting its detailed environmental impact statement to a review process unless it was specifically required to do so by public challenge. The court decided:

> We believe that the Commission's crabbed interpretation of NEPA makes a mockery of the Act. What possible purpose could there be in the Section 102(2) (C) requirement (that the "detailed statement" accompany proposals through agency review processes) if "accompany" means no more than physical proximity—mandating no more than the physical act of passing certain folders and papers, unopened, to reviewing officials along with other folders and papers? What possible purpose could there be in requiring the "detailed statement" to be before hearing boards, if the boards are free to ignore entirely the contents of the statement? NEPA was meant to do more than regulate the flow of papers in the federal bureaucracy. The word "accompany" in Section 102(2) (C) must not be read so narrowly as to make the Act ludicrous. It must, rather, be read to indicate a congressional intent that environmental factors, as compiled in the "detailed statement", be *considered* through agency review processes.

On the AEC's decision not to consider environmental issues for permits issued before March 14, 1971, the court said:

> Strangely, the Commission has principally relied on more pragmatic arguments. It seems an unfortunate affliction of large organizations to resist new procedures and to envision massive roadblocks to their adoption. Hence the Commission's talk of the need for an "orderly transition" to the NEPA procedures. It is difficult to credit the Commission's argument that several months were needed to work the consideration of environmental values into its review process. Before the enactment of NEPA, the Commission already had regulations requiring that hearings include health, safety and radiological matters. The introduction of environmental matters cannot have presented a radically unsettling problem. And, in any event, the obvious sense of urgency on the part of Congress should make clear that a transition, however "orderly", must proceed at a pace faster than a funeral procession.

Finally, the court instructed the commission to consider calling a halt to construction of some plants:

> . . . In order that the pre-operating licence review be as effective as possible, the Commission should consider very seriously the requirement of a temporary halt in construction pending its review and the "backfitting" of technological innovations. For no action which might minimize environmental damage may be dismissed out of hand. Of course, final operation of the facility may be delayed thereby. But some delay is inherent whenever the NEPA consideration is conducted —whether before or at the licence proceedings. It is far more consistent with the purposes of the Act to delay operation at a stage where real environmental protection may come about than at a stage where corrective action may be so costly as to be impossible.

The new regulations place firmly in the hands of the AEC the responsibility for evaluating likely environmental effects of a nuclear power plant, including the so-called thermal pollution of cooling waters, and the commission is also charged with the task of balancing these likely effects with the growing need for electric power and with assessing alternative approaches. Environmentalists have in the past accused the AEC of being unresponsive to environmental questions because it has been in no position to evaluate alternatives; and therefore any attempt at a cost benefit approach to the licensing of a new power plant has been chiefly left to the electricity companies which cannot be expected to take a wholly unbiased attitude.

Environmental effects of proposed nuclear power plants will now be considered as a matter of course at two different stages of a licence procedure —when a company applies for a licence to construct a plant, and again when it applies for a licence to operate it. At the construction stage, the applicant must submit to the AEC a report spelling out in detail the environmental effects of the proposed plant, any adverse environmental effects that cannot be avoided should the proposal be implemented, alternative approaches to the proposed construction, "the relationship between local short-term uses of man's environment and the maintenance and enhancement of long-term productivity", and any irreversible and irretrievable commitment of resources which would be involved in the proposed action should it be implemented. The last two obscurely worded requirements are designed to help the AEC to conduct its own cost benefit analysis of the project, in terms of alternative methods for reducing environmental damage. An applicant for a licence to operate a nuclear plant must also submit to the AEC a report detailing the environmental effects of the plant, but only where they differ from the effects spelt out in the application for a licence to construct the plant.

The next stage in the process requires the AEC's Director of Regulations to draw up his own draft statement on the likely environmental effects of the plant, open the statement up for public comment, in the light of which he will draw up a final detailed statement and give his opinion on whether or not the permit should be issued. The detailed statement will include a cost benefit analysis balancing the environmental effects of the facility with its economic and technical effects.

The court of appeals chided the AEC for simply turning over the applicant's environmental report to other federal and state agencies, such as the agencies approved to regulate water quality standards under the Federal Water Pollution Control Act, for assurance that the proposed plant will meet their standards. "The upshot is," the court pointed out, "that the NEPA procedures, viewed by the Commission as superfluous, will wither away in disuse, applied only to those environmental issues wholly unregulated by other federal, state, or regional bodies." This abdication of responsibility also prevented the AEC from considering the environmental effects of the proposed plant in the light of alternative actions. But the new regulations specifically require that the AEC's detailed statement includes a discussion of the effects "irrespective of whether a certification from the appropriate authority has been obtained".

The detailed environmental statement will then be offered in evidence if a public hearing is held, and the Atomic Safety and Licensing Board has been charged with the task of determining whether the requirements of the National Environmental Policy Act have been carried out in the proceedings. The licensing board will then have the honour of determining whether the licence should be granted, denied or modified to protect the environment. That decision would, of course, be open to public appeal, and all construction permits and operating licences would be issued on the condition that the licensee observes environmental conditions laid down by the federal government, the state in which it is to be built or operated and the Atomic Energy Commission.

The upshot of these new regulations is that the Atomic Energy Commission itself will be directly responsible for ensuring that the environment will not be abused by the construction or operation of a new plant, that environmental considerations are given prominence at every stage of the licence application, and that there is ample time for the public to offer a comment or a challenge on every report and decision made during the process. Another effect is that the regulations will add a further bottleneck to the processing of applications and place an extra burden on the commission's staff. Asked last week whether the regulations will slow up the granting of a licence which will permit operation or construction, Harold L. Price, the AEC's Director of Regulations, said that he hopes the present delay of eighteen months between application and granting of a construction licence will not be extended. Others, particularly the electricity producers, were not so optimistic, however, and the spokesman for one company said last week that licensing delays are already placing an intolerable burden on the utilities in trying to meet the consumers' power needs. (The Federal Power Commission states, however, that licensing procedures caused delays to only eight out of 114 major power plants that started producing electricity between 1966 and 1970.)

Of even greater concern to the electricity producers is the provision in the new regulations for submitting to a detailed environmental review all the plants at present under construction or which have received operating licences since January 1, 1970, the date on which the National Environmental Policy Act came into force. Not only will these plants be reviewed, but the AEC is also asking that construction or operation be stopped until the review is completed. The electricity companies have been given thirty days to show why construction or operation should not be stopped before the AEC throws its powerful spanner in the works, and their only hope is to be able to show that continued construction or operation will not damage the environment significantly, that it will not preclude the adoption of environmental safeguards should they be necessary, and that delay would damage the public interest by failure to meet power demands or by causing undue costs to the licensee or the consumer. Five nuclear power stations that are already producing electricity and forty-six others that are under construction are threatened by this provision. Environmental reports must be submitted to the AEC detailing the environmental impact of the plant, and the Director of Regulations of the AEC must then go through the complete procedure of issuing a draft and later a final detailed environmental report on the plant. It is then up to the Director of Regulations to decide whether the licence or permit should be continued, modified to protect the environment, or be revoked, and his decision will be open to challenge in a public hearing.

In backtracking so vigorously on its past regulatory policies, the AEC has opened itself wide to court action from disgruntled electricity producers, and the sharpening of knives could clearly be heard in the industry last week. A spokesman for the Consolidated Edison Company, although reserving his comments until the company has had a chance to study the regulations in greater depth, accused the AEC of plunging the electricity industry into a crisis, and he pointed out that several electricity companies are intending to appeal against the appeals court decision which precipitated the AEC's new environmentally conscious image. Even if that appeal is successful, however, it is unlikely to affect the new regulations, although it would place the AEC in the embarrassing position of enforcing regulations that would no longer be upheld by a court decision, and this would serve to strengthen the hand of the electricity companies in any future court skirmish with the commission

Of more immediate concern to the AEC, however, is the possibility that electricity companies will file a suit for losses caused by construction or licensing delays, or for the installation of expensive equipment such as cooling towers. In that case, the AEC would undoubtedly be on very sticky legal ground, for the companies have all proceeded under licences or permits issued legally by the AEC under its old regulations, but they now face the possibility of having those licences modified or revoked because the commission now regards them as inadequate for the protection of the environment. The AEC's policy switch has therefore put both the commission itself, and the industries it regulates, in an extraordinary position, but while the courts are being kept busy, environmentalists can take heart that the new chairman of the commission is not deaf to their pleas.

EMPLOYMENT

Unemployed PhDs

by our Washington Correspondent

MORE evidence about the tight job market for those holding a PhD in science has been published this week by the National Research Council. A survey, conducted between December 1970 and March 1971, of scientists who received their PhD degree in 1970, showed that 1.6 per cent were out of work, and that a further 1.2 per cent held jobs for which their academic training was unnecessary. Moreover, there are signs that many more PhDs are looking towards postdoctoral training as an escape from the realities of the job market, but the indications are that they will fare no better when they finally leave the groves of academe, for the National Research Council has discovered that of the PhDs that had been engaged in postdoctoral training in 1970, 2.2 per cent were unemployed in the following winter and 0.9 per cent were employed in an "inappropriate position".

The results of the survey, which in many respects bear out the findings of an employment analysis conducted by the National Science Foundation (*Nature*, **232**, 150; 1971), are a clear indication that the prospect of a dire shortage of PhDs that was predicted for the 1970s has not materialized, and that the universities are already turning out more PhDs than the market can absorb. The Office of Education, for example, predicted in 1964 that there would be a desperate shortage of PhDs by 1974, and a great drive was undertaken in the universities to make up the predicted shortfall. Last year, for example, 29,436 scientists received PhDs—an increase of 14 per cent compared with the previous year. Although, compared with the national unemployment rate, which has been running at about 6 per cent for the first half of 1971, the unemployment rate for PhDs is small, prospects for the rest of the decade look grim. The 1970 figure, for example, showed that the number of scientist PhDs out of work is increasing at an alarming rate (the 1970 figure was double the 1969 total), and the NSF has recently predicted that by 1980, at present rates, there will be about 45,000 more PhDs in America than there are suitable jobs.

The NRC survey has also brought out the fact that physicists are the worst hit single group of scientists, with 2.9 per cent of the PhDs and 3.3 per cent of the postdoctorals out of a job. Mathematicians, geoscientists and social scientists, on the other hand, reported lower than average unemployment rates, with 1.2, 0.7 and 0.5 per cent of their PhDs out of work in 1970. Even these subjects, however, reported greater unemployment rates for 1971 than for the previous year. There was also a sharp increase in the number of foreign-born scientists unemployed in the United States—the figure rose from 0.9 per cent in 1969 (the same as for US citizens) to 2.3 per cent in 1971 (compared with 1.6 per cent for US nationals)—a figure that can only be partly accounted for by the fact that fewer foreign-born holders of the PhD left after completing their academic training in 1971 than in 1969.

One of the most significant findings in the survey is that the number of new recipients of the PhD who went on to postdoctoral work in the universities in 1970 increased by 4.5 per cent over the 1969 figure. This fact undoubtedly hides much of the unemployment, and disillusionment among PhDs fresh from the university production line, but with few prospects of appropriate employment outside the universities. Moreover, the situation will probably be made considerably worse by the fact that predictions made two years ago by the Office of Education, that graduate enrolment would have risen by 99 per cent by 1980, now seem to be vast overestimates—the NSF, for example, now predicts that the expansion may be nearer 45 per cent—thereby reducing drastically the predicted number of jobs for PhDs in the universities themselves.

The National Research Council itself concludes from the survey that "various market accommodations are undoubtedly responsible for preventing what would otherwise be a gross oversupply". Nevertheless, with an eye clearly on the mandarins in the Office of Education, the NRC says "any deficit of jobs must . . . be a matter of national concern, and reliance solely on market adjustments to an oversupply would be both callous and unwise. The large investment in graduate education and the valuable human resources at stake demand that any underemployment or unemployment of doctorate recipients be corrected".

NEWS AND VIEWS

Of Mice and Men

As the number of research workers setting their sights on the discovery of human tumour viruses increases—as it seems certain to do, especially in the United States where money for cancer research is becoming so easy to come by and money for anything else commensurately difficult to find—it can confidently be anticipated that there will be numerous repetitions of the sequel of events which has followed the report by Priori, Dmochowski and their colleagues (*Nature New Biology*, **232**, 61 ; 1971) that a cell line from a child with Burkitt's lymphoma produces a C-type RNA virus and which has culminated in the report by Gilden, Parks, Huebner and Todaro (see page 102 of this issue of *Nature*) that this is probably a mouse virus, presumably a contaminant.

Dividing cells, whether in an animal or maintained *in vitro* in cultures, provide an ideal environment for the replication of all sorts of viruses which have nothing whatsoever to do with malignancy. Any virus which by chance reaches a population of such cells is likely to become permanently established in it. And those biologists who are now turning to tumour virology, if only to keep themselves in a job, would do well to remember that whenever they find a virus in a fresh biopsy of tissue from a tumour or in a population of tumour cells in culture, the first priority is not to call a press conference but to recognize that the virus is probably a contaminant. As recent events seem to have shown, even such old hands in the game as Priori and Dmochowski can be tripped over by contamination, and their story is salutary.

Priori *et al.* established a monolayer cell culture from the pleural effusion of an American child with Burkitt's lymphoma. During the tenth passage of these cells they were found to bud typical C-type particles with all the morphological characteristics of the avian and animal RNA tumour viruses. Well aware of the problem of contamination, they apparently sent samples of their virus to Dr Old's group at the Sloan–Kettering Institute to have them classified by serological tests. The crucial question was simply does this virus have the group-specific antigen, which indicates species specificity, of any of the known animal sarcoma and leukaemia viruses or does it have a unique group-specific antigen which would strongly suggest that it is indeed a human C-type virus? Although Priori *et al.* gave few details of the tests performed in Old's laboratory they reported that their virus seemed to have a group-specific antigen different from any of the antigens of the known animal leukaemia viruses. Not surprisingly this result encouraged them to believe that they might well have isolated a human C-type virus, but both this result and its interpretation have now been seriously challenged by Gilden *et al.*

Gilden *et al.* obtained from Priori and Dmochowski some of the virus producing cells at their forty-first passage and taking every precaution to prevent any contamination of the cells in their two laboratories, they performed three sorts of immunochemical tests to see whether the virus was related to any of the known animal C-type viruses. The results of both complement fixation and radioimmunoprecipitin inhibition tests strongly suggested that something in the human, virus-producing cells carried the group-specific antigens of the mouse leukaemia viruses. Pursuing this lead, they then performed immunodiffusion tests with sera specific for the mouse virus group-specific antigen and sure enough found a precipitin line of identity between highly purified murine group-specific antigen and concentrates containing the virus liberated by the human cells. In short, these results must mean either that the virus being produced by Priori and Dmochowski's cells is murine leukaemia virus, which presumably somehow contaminated the cultures, or mouse and human C-type viruses have group-specific antigens which cannot be differentiated by these tests. This second alternative seems to be most unlikely and, if the results of Gilden *et al.* can be independently confirmed, it will be hard to avoid the conclusion that the virus Priori *et al.* have isolated is anything other than a contaminant and a red herring.

But as one putative human cancer virus is eliminated, others are turned up. The two virus-like particles from cultures of cells from patients with Hodgkin's disease, which Kingsley Sanders's group describe on page 104 of this issue of *Nature*, for example, must be suspect until they have been further characterized. Perhaps stimulated by the fascinating epidemiological study of a rash of Hodgkin's disease cases among the 1954 graduating class of a New York State high school, which lead Vianna, Greenwald and Davie (*Lancet*, i, 1209 ; 1971) to conclude that Hodgkin's may well be an infective disease with a long incubation period and a carrier state, Kingsley Sanders and his colleagues established a number of long-term cell cultures from lymph node material of Hodgkin's patients and searched for virus particles. The cells in the cultures underwent some bizarre changes including a "blastoid transformation" during which "practically every reticular cell could be seen to have one or more round cells within it", but they also began producing two sorts of virus-like particles. One of these is apparently a DNA containing particle which under the electron microscope resembles a herpes virus and there is evidence that the cells after the blastoid transformation have herpes virus antigens. The second particle which has so far defied all but the most preliminary characterization apparently contains RNA but under the electron microscope nothing with the characteristic morphology of a virus has yet been seen.

Obviously these observations are extremely preliminary; whether or not these cells are producing an RNA virus remains to be seen and the significance of the herpes virus is at present anybody's guess. Nevertheless, the findings of Vianna *et al.* strongly suggest that a virus which plays a part in the aetiology of Hodgkin's disease awaits discovery and it can be certain that Kingsley Sanders and his colleagues will soon find themselves in a crowded field, for if so many workers are set on searching for human cancer viruses they may as well concentrate on one of the extremely few forms of human cancer for which there is at least some epidemiological evidence to suggest the existence of a virus. And it scarcely needs adding that a more extended investigation of the epidemiology of Hodgkin's disease would not come amiss.

CANCERS

Dangers of Affluence

from our Cell Biology Correspondent

THE fig and prune producers of the world might do worse than start an advertising campaign with the slogan "a bowl a day keeps bowel cancer away" to judge from what Burkitt has to say in the current issue of *Cancer* (**28,** 3; 1971). Burkitt has, of course, spent many a long year trying to pin down environmental factors responsible for particular cancers, always arguing that the incidence of the disease can be significantly reduced more easily by eliminating or evading the causative agents than by trying to fathom out their mode of action and devise a cure. And his latest foray, this time into the epidemiology of cancer of the colon and rectum, leads him to the conclusion that the refined diets of the world's developed nations, in particular their lack of indigestible fibre, may, together with particular gut floras, be responsible for the comparatively high incidence of bowel cancers and other non-malignant and non-infectious diseases of the bowel in affluent societies.

The incidence of bowel cancer, which in most western countries is second only to the incidence of lung cancer, is correlated with the stage of economic development, and Burkitt claims that the age adjusted incidence of this disease is ten-fold greater in Western Europe and North America than in most African countries. Epidemiologists when faced with such findings frequently resort to the incantation "dietary differences" and leave it at that with the real problem, the identification of the crucial dietary components, unsolved. Burkitt to his credit has given hostages to fortune by suggesting what the crucial factors may be, namely the transit time of the stools through the bowel and the nature of the bowel flora.

By recruiting the help of African and English boarding school boys, who were provided with radio-opaque plastic pellets as a condiment for their school meals, he and his collaborators have shown that there is a clear inverse relationship between the transit time and bulk of the stools and the fibre content of the food eaten—the more fibre the shorter the transit time. African boys passed 80 per cent of the plastic pellets in 45 h whereas their English counterparts took 89 h. Burkitt suggests therefore that carcinogens produced by the bacterial flora in the bowels of westerners, whose foetid stools contrast markedly with the odourless stools of Africans, are held at high concentrations for prolonged periods in contact with the bowel mucosa with the net result of an increased incidence of bowel cancer in western populations. Like a prophet in the wilderness Burkitt writes: "In view of the evidence, it seems justifiable to issue a warning against the removal of so much of the unadsorbable fibre from our food, and the associated over ingestion of refined carbohydrate".

Another and related warning was published recently by Hill, Goddard and Williams (*Lancet*, i, 472; 1971) who suggest that differences in fat consumption together with differences in gut flora may account for the geographical variations in the incidence of breast cancer. It is well known that mammary carcinoma is far more prevalent among North American and North West European women than among African, Asian and South American women, and surveys of the Japanese populations in Japan, Hawaii and the West Coast of the United States show that differences in the incidence of breast cancer depend on geographic rather than genetic factors. Dietary differences have been discussed, and Wynder, for example, has postulated that the consumption of large amounts of fat may affect hormone production and/or storage in adipose tissue and thus be responsible for an increased incidence of breast cancer.

Hill and his colleagues now suggest an alternative mechanism. They have shown that people eating high fat diets have in their guts more active and strictly anaerobic bacteria than people eating low fat diets. Moreover these bacteria are able to produce oestradiol, oestrone and several other steroid sex hormones. If one or more of these steroids is carcinogenic or acts synergistically and stimulates the growth of tumour cells, anaerobic gut bacteria may be the link between high fat diets and a high incidence of breast cancer, and for that matter colonic cancer. If the much discussed expansion of cancer research materializes, the distributors of the dollars might do worse than promote further investigations of the metabolic activities of gut bacteria.

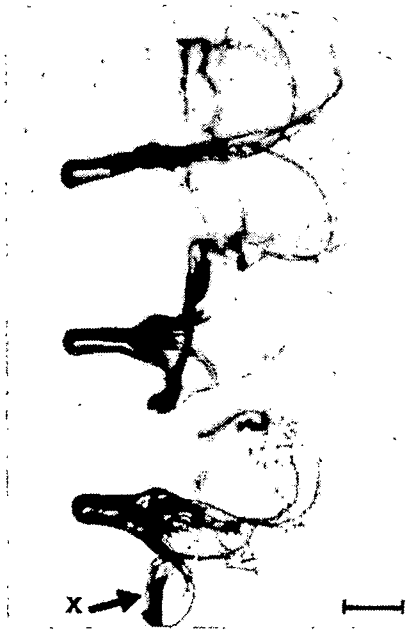
Liquid Drops in Shock Tubes

THE photograph below shows some of the bizarre shapes that drops of water can take up in a shock tube. The drops are falling through a flow that is from left to right, and the aerodynamic and surface tension forces involved have given the drops an umbrella-shaped canopy. The photograph is one of several in next Monday's *Nature Physical Science* that have been obtained by P. G. Simpkins of Bell Telephone Laboratories, Whippany, New Jersey, illustrating the successive deformations that drops undergo when exposed to a sudden increase in the external flow.

The crucial parameter in work of this nature is the ratio of the force due to aerodynamic pressure to the force due to surface tension—the Weber number—and the photograph was taken at a Weber number of 45. But the region in which Simpkins is interested has a lower limit at a Weber number of about 7.3—above this critical value the non-uniform distribution of surface pressure exerted on the drops causes deformations which eventually lead to the bursting of the drops.

The steps in this process, as charted by Simpkins, are as follows. At a Weber number of 19 drops that initially had a diameter of 1 mm are flattened by the flow into thin disks. The centres of the disks then blow out in the direction of the external flow, so that the drop takes on the appearance of a bag supported by a liquid annulus. Simpkins presents graphs showing how the distortion proceeds, and discusses the deviations in behaviour from those predicted by simple theory.

The deviations from expected behaviour become more severe at higher Weber numbers. Umbrella-shaped distortion of the drops like that in the photograph occurs at Weber numbers above twenty. The mechanism by which the drops form a narrow stem and subsequently a canopy is, however, unknown.



Drops in a shock tube at a Weber number of 45, 1,660 μs after the start of the flow. The flow is from left to right and the bar represents 1 mm. The arrow points to a satellite drop which is showing the bag response.

PROTEINS

The Mighty Photon

from our Molecular Biology Correspondent

THE use of the photon as a reagent, or as a trigger that will set off other reagents at a chosen point in space or time, is an approach that will undoubtedly find increasingly wide application in molecular biology. One—albeit qualified—advantage is that short-lived photochemically generated species are inclined to have very high reactivity, and when unleashed on an enzyme, for example, are apt to react even with aliphatic side chains. Too indiscriminate a reactivity of course restricts the value of a reagent, and Sperling and Elad (*J. Amer. Chem. Soc.*, **93**, 3839; 1971) have addressed themselves to ways of controlling the specificity of photochemical alkylation. They have found that on irradiation of a system containing a peptide, an unsaturated species, such as butene or toluene, and an initiator, substitution occurs at the α-carbon of glycine residues, butene giving rise to norleucine, toluene to phenylalanine. When proteins are allowed to react under these conditions, however, histidine, cystine, methionine, tyrosine and tryptophan residues also react. This is a consequence of the formation of various free radicals, and if radical scavengers are added to the reaction mixture the majority of these side reactions are suppressed. It proved impossible, however, to prevent instant death to the tryptophans. In ribonuclease, which has no tryptophan, glycine reacted and, though a certain amount of other damage occurred, 20 per cent of enzymatic activity was retained.

Of more immediate biological moment is the design of photochemically triggered affinity labels, which hold out the advantage that they will not react fruitlessly on their way to the specific binding site. Brunswick and Cooperman (*Proc. US Nat. Acad. Sci.*, **68**, 1801; 1971) have prepared analogues of the biochemical elixir, cyclic AMP, labelled with tritium and bearing diazomalonyl groups in the purine and in the sugar. On irradiation a ferociously reactive carbene is generated, which is expected to react with almost any group within reach. The analogues will bind to the enzyme phosphofructokinase, for which cyclic AMP is the natural activator. They both activate and compete with cyclic AMP, and after irradiation are covalently integrated into the enzyme.

This work now opens the way to the isolation of a labelled peptide and the characterization of the activator binding site. A more exciting prospect for the biochemist, however, is the use of the same reagents to label cyclic AMP receptors in cells, and indeed Brunswick and Cooperman have already succeeded in introducing a label into a protein component of rat testis. The reagent is thus permitted to traverse the membrane and diffuse through the cell to its target protein before it is irradiated and caused to react. The advantages of this strategy in labelling components in intact tissue need no labouring.

Erlanger and his colleagues have meanwhile continued their attempts to simulate the photochemical systems of nature in the laboratory. By the use of acetylcholine analogues capable of light-induced *cis-trans* isomerization they achieved partial control over the activity of an excitable tissue preparation, because the isomers will not in general be expected to possess precisely the same binding characteristics. Bartels, Wassermann and Erlanger (*ibid.*, 1820) have now brought this essay in biochemical engineering to a considerable state of refinement. They have, apparently by a process of serendipity, arrived at a species—an azobenzene derivative—of which the *trans* isomer is one of the most powerful known activators, and the *cis* isomer is largely, perhaps completely, inactive. They have moreover built into such a molecule the means for attaching it covalently to its receptor. This is based on the earlier observation by Karlin that affinity labelling of the acetylcholine receptor of the electroplax membrane could be achieved with a thiol-reactive function, if the tissue was first treated with a reducing agent to break a disulphide bond, evidently located hard against the binding site.

Substantial *cis-trans* interconversion of the azobenzene derivative can be achieved by ultraviolet irradiation, and is reversed by white light. Thus when the system containing electroplax tissue, stimulated by the *trans* isomer, is exposed to the near-ultraviolet light, precipitous depolarization ensues. Competition with carbamylcholine and curare occurs as expected. When the thiolreactive version of the analogue is covalently attached to the reduced membrane, the competitive effect of carbamylcholine is lost. This then is a completely self-sufficient light-regulated system. The reactive *trans* isomer is reported to inhibit acetylcholinesterase, but so equally does the *cis* form. The inferred message is that the acetylcholine receptor and acetylcholinesterase are distinct and unrelated forms.

Plasma Current Amplifier

IN next Monday's *Nature Physical Science*, P. C. Stangeby and J. E. Allen describe a new device which contains a narrow metal-walled electric discharge vessel and which is capable of high current amplification. The metal walls behave as a cathode and electrons are extracted from the metal by surface recombination with ions that arrive from the plasma.

According to the theoretical description of the device, the ion current travelling to the walls of the conducting cylinder is related to the discharge arc current in an expression involving the radius of the cylinder, the electron and ion masses and other constants which are of the order of unity. The cylinder is biased in such a way that the electrons produced by ionization of the neutral particles which carry them away from the wall are retained in the arc discharge; the ions can then return to the cylinder to pick up other electrons. The plasma current thus increases exponentially with distance down the cylinder and, for small cylinder radii and small ion masses, the multiplication factor is very large (for H_2 in a 5 mm diameter cylinder, for example, a current amplification of about 10^7 can be obtained).

The prototype apparatus used by Stangeby and Allen comprised a metal tube 6 mm in diameter and an anode which could be moved inside the tube. There were two alternative cathodes—a mercury pool type and a thermionic type. A 2 A current from the mercury pool cathode was made to flow across the mouth of the metal discharge tube and was collected by an auxiliary anode; the required current input to the metal tube itself was then tapped off.

The thermionic cathode gave similar experimental results, but one of its advantages was that the tube current could be measured directly with an ammeter. There was also a facility for introducing a quantity of argon gas to examine the effect of reducing the ion mass (which should increase the amplification). Measurements with the apparatus have shown that the current amplification at a mercury pressure of 1 mm Hg and an argon pressure a few hundred times this value is as expected theoretically. Although they did not measure the argon flow rate accurately, Stangeby and Allen found that an increased rate was associated with a distinct increase in the amplification.

There are probably several uses for current amplifying devices of this type, including applications to high power lasers; they may also be useful as high current controls.

PERMO-TRIASSIC

Problems left Unsolved

from a Correspondent

AN international conference, with problems of the Permian–Triassic boundary as its principal theme, was held from August 23–26 at the University of Calgary, Alberta, Canada. The keynote of the conference was set by Dr A. McGugan, speaking on behalf of Dr N. D. Newell (American Museum of Natural History, New York), who outlined some of the major problems of the late Permian and early Triassic. These included the almost universal occurrence of discontinuities or paraconformities at or near the system boundary, the general poverty of the contemporary fauna and the wide extent of essentially barren continental red beds.

The concept of a universal hiatus in marine strata at or near the system boundary was emphatically supported by Dr E. T. Tozer (Geological Survey of Canada, Ottawa), and, although there was some disagreement on exact placing, it was generally conceded that a break is present in each of the classic mid-Tethyan sequences of Armenia, Kashmir and the Salt Range of West Pakistan. The duration of the hiatus was thought on some palaeontological evidence to be of the order of one to two stages, but Dr W. G. Sweet (Ohio State University) considered that the break could not be recognized in conodont assemblages. In an unscheduled and characteristically forthright paper, Dr R. Assereto (University of Milan) asserted that the hiatus might have been shorter in some eastern parts of the southern Alps than in the classic sections farther east, and Dr H. Taraz (Geological Survey of Iran), whose view was challenged in discussion, suggested that no breaks were present in a thick late Permian and early Triassic marine sequence in central Iran. He proposed a loosely defined Abadeh stage for the time represented by post Djulfian pre-Triassic strata.

The staggered but progressive decline in late Permian floras and faunas was documented by several speakers, including Drs R. Toryama (Kyushu University) and G. L. Wilde (Humble Oil and Refining Company, Houston) who described the final stages in the evolution of the fusulinids, and Dr G. L. Batten (American Museum of Natural History, New York) who showed how a dramatic decrease in marine gastropod genera took place in the late Permian and was not fully recouped until the Ladinian. Among plants, Dr J. M. Schopf (US Geological Survey, Columbus) demonstrated a sharp unexplained change from the dominant *Glossopteris* flora of the Permian to a Triassic flora dominated by *Dicrodium*.

Several speakers speculated on the cause of the floral and faunal decline in the late Permian, without reaching agreement. Drs J. Pattison, D. B. Smith and G. Warrington (Institute of Geological Sciences, Leeds) suggested that a major cause might be the virtual elimination of shelf seas, during a prolonged phase of tectonic stability and peneplanation following rapid build-up of evaporites and progradation of coastal plain sediments. This view was supported by Dr B. Waugh (University of Hull) and, with variations, by several other speakers. There were tentative suggestions that the changes in the contemporary biota might have been related to the beginning of the break-up of Laurasia, and Dr G. F. Stehli (Case Western Reserve University) showed that seafloor spreading could be reconciled with the distribution of known Permian and Triassic biotas as well as that of evaporites and red beds.

The effects of late Permian and early Triassic plate movements along the Pacific margin of the United States were graphically interpreted by Dr N. J. Silberling (Stanford University), but Dr A. A. Meyerhoff (Tulsa), opposing the concept of continental movements, claimed that the biotic crisis could have been caused by cosmic ray and temperature maxima associated with rare galactic events of a type calculated to have prevailed near the end of the Permian. Finally, the view that late Permian floras and faunas might have declined following nutrient depletion and a progressive failure of lower members of the food chain was persuasively argued by Drs Helen Tappan and A. R. Loeblich (University of California).

In the closing sentence of his introduction, Dr N. D. Newell had expressed the wish that the conference would leave unsolved at least some of the Permian and Triassic problems: his wishes, perhaps unwittingly, were duly gratified.

How SV40 DNA Replicates

THE mechanism of replication of such covalently closed circular DNA molecules as the chromosomes of *Escherichia coli* and the coliphages lambda and ϕX 174 has long been a source of fascination to molecular biologists. And there continue to be arguments for and against the Cairns's model of replication, which predicts that none of the DNA strands in the replicating structure is longer than a parental strand and the two progeny strands are of equal length, and the rolling circle model, which predicts the occurrence of some DNA longer than parental strands and progeny strands of unequal length. The replication of the genomes of the DNA tumour viruses SV40 and polyoma virus, which are not only closed, circular, double stranded DNAs but are also supercoiled, presents, of course, the same topological problems as the replication of circular phage and bacterial DNAs. And the experiments published in *Nature New Biology* next week by Jaenisch, Mayer and Levine clearly indicate that it is by the Cairns's mechanism that these molecules duplicate.

Jaenisch and his colleagues used the Hirt procedure to extract preferentially the SV40 DNA from infected African green monkey kidney cells, which 40 h after infection had been exposed to ^{3}H-thymidine for periods ranging from 3.5 min to 120 min. They then analysed the viral DNA on sucrose, ethidium bromide–caesium chloride and alkaline gradients and examined it by electron microscopy. In summary they find that replicating SV40 molecules contain parental closed circular DNA strands as well as linear fragments of newly made DNA. Moreover, the DNA labelled during the shorter pulses is shorter than one complete SV40 strand and is not linked to parental strands; the rolling circle model, of course, predicts the opposite of these findings.

Molecules which are partially (10–70 per cent) replicated sediment faster than anticipated, but under the electron microscope the reason for this becomes obvious; these molecules have two untwisted branches of equal length attached to a third twisted or supercoiled branch and, as expected, the length of one untwisted strand plus the twisted strand is about the same as the length of a single relaxed SV40 genome. The electron microscope also reveals single stranded discontinuities at the forks and some 34 per cent of the molecules examined have these regions at both forks. If a single stranded region at a fork indicates a site of replication then at least some SV40 DNA molecules must be replicated in two directions from an origin, although this cannot be obligatory, for 41 per cent of molecules had only one fork with single stranded DNA.

By showing in reconstruction experiments that relaxed SV40 DNA molecules are not converted into covalently closed, double stranded circles during the experimental procedure, Jaenisch *et al.* have disarmed critics who might have suggested that *in vivo* the template for replication is a nicked DNA strand, which, during the experiment, is closed into a ring. And so it is hard to escape the conclusion that at least some SV40 DNA molecules replicate by the Cairns's mechanism.

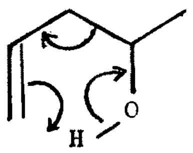
REACTION MECHANISMS

Where is the Proton?

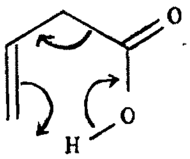
from our Biological Chemistry Correspondent

Kinetic isotopic effects provide a specialized tool for investigating transition states of reactions which involve slow proton transfers. At the qualitative level, the technique of exchanging hydrogen for deuterium has many successes to its credit, not least in the field of enzymatic mechanisms. The problems emerge when attention is directed to the significance, if any, of the quantitative aspects of primary isotopic effects.

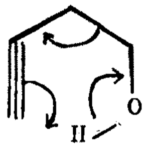
The early theoretical appraisals, notably due to Westheimer and to Biegeleisen, developed the concept that the magnitude of the kinetic change observed on isotopic substitution should reflect the extent of hydrogen transfer in the transition state: "maximum" effects correspond to those reactions in which the hydrogen is symmetrically located between the donor and acceptor groups in the transition state. Although this idea has been widely applied, direct supporting data have been sparse and the concept has been challenged often, most recently by F. G. Bordwell and W. J. Boyle (*J. Amer. Chem. Soc.*, **93**, 512; 1971) who searched in vain for a simple correlation between isotopic effect and extent of proton transfer.



(1)



(2)



(3)

H. C. Kwart and M. C. Latimore (*ibid.*, **93**, 3770; 1971) have now provided strong validation of Westheimer's concept by investigating three gas-phase reactions. The thermolytic fragmentation of 4-penten-1-ol (1), 3-butenoic acid (2), and 3-butyn-1-ol (3) all proceed through concerted bond-reorganization processes which unquestionably involve transfer of hydrogen from oxygen to carbon—formally indicated by the "curly" arrows, but probably sigmatropic processes. In spite of this similarity, the three cases provide a significant variation both of the acidity of the hydrogen being transferred and in the electronic structure around the acceptor-carbon. If therefore these factors influence the isotopic effect, differences should become apparent.

The rates of all three reactions, measured over a range of temperatures, show a 2-fold to 2.5-fold rate retardation on replacement of hydrogen by deuterium. "Maximum" values for the isotopic effects were calculated on the assumption that the zero-point energy difference, O-H *vs* O-D, alone determines the kinetic isotope effect. In each case, observation and calculation agree within the limits of experimental error.

These results thus provide one of the strongest supports for the continued use of kinetic deuterium isotopic effects as a criterion for concertedness in hydrogen transfer reactions.

HEPATITIS

Active Immunization

from our Medical Virology Correspondent

It has been repeatedly demonstrated in many parts of the world that the injection of normal human immunoglobulin (gamma-globulin) during the incubation period of infectious (epidemic) hepatitis can prevent jaundice among contacts. Although the incidence of the icteric form of hepatitis was thus reduced, infection was not prevented—it was attenuated to a variety of hepatitis without jaundice or to the subclinical form of the disease and faecal excretion of the virus still occurred.

The precise mode of action of immunoglobulin is not completely known but it is presumed that partial passive, and therefore short term, immunity against infectious hepatitis is obtained by the antibodies present in the globulin prepared from large pools of plasma. Active immunity may, of course, be acquired through subclinical infection, so-called passive–active immunity.

The problem with serum hepatitis, on the other hand, seems to be entirely different, and immunoglobulin has not reduced significantly the incidence of post-transfusion hepatitis. The discovery of the association between Australia antigen and serum hepatitis has provided the crucial key for studies of this form of hepatitis. S. Krugman and his associates (*J. Amer. Med. Ass.*, **217**, 41; 1971) now report the results of limited studies in volunteer children on active immunization against serum hepatitis caused by the MS-2 strain. Thirty-nine children were divided into two groups: one group of twenty-five susceptible children were injected with MS-2 serum; the second group included fourteen susceptible children who received either one or two inoculations of heat inactivated preparation of a 1 in 10 dilution of MS-2 serum followed by an inoculation of untreated infective serum 4 to 8 months later. It was found that hepatitis induced by MS-2 serum was prevented by active immunization and that two spaced inoculations were more effective than one. Nevertheless, one inoculation gave enough protection to prevent some cases of serum hepatitis and to modify others. Krugman and his colleagues emphasize that these obser-

"Unblocking" Sera in Anti-tumour Immunity

During the past few years evidence has accumulated that animals and human patients with progressively growing tumours often have immune cells that are capable of reacting against their own tumour cells, as shown by cytotoxicity tests *in vitro*, but they also have in their sera factors that can specifically block the anti-tumour reactions. To increase anti-tumour immunity it would be useful if ways could be found for overcoming such blocking effects. The possibility that another group of serum factors can "unblock" immune reactions against tumours arises from the work of the Hellströms and their associates on sera from mice with regressing Moloney sarcomas, and of Bansal and Sjögren on polyoma virus-induced tumours in inbred rats. The latest report from these last authors will appear in next Wednesday's *Nature New Biology*.

Bansal and Sjögren have found that when sera from rats immune to polyoma tumours are mixed with homologous blocking serum, they counteract the inhibition produced by the blocking serum on lymphocyte-mediated cytotoxicity against polyoma tumour cells *in vitro*. Still more remarkable, such sera inoculated into five rats bearing transplanted polyoma tumours brought about regression of the tumours in four of the animals. These effects are not caused by anti-viral antibody, and it seems unlikely that they are caused by serum-mediated autotoxicity because the transplanted cells grew into palpable tumours before regressing—such regression is never seen in untreated rats. Further work is required to establish how common unblocking activity in serum is, whether it is caused by a particular kind of antibody, and how it unblocks. One interesting possibility is that blocking is caused by antigen–antibody complexes, with which unblocking could react. Whatever the mechanism, there is no doubt that unblocking is of general interest as well as potential therapeutic significance.

vations are based on relatively small numbers.

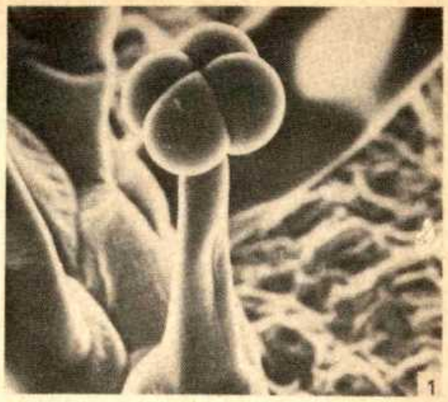
These studies represent the culmination of many years of research using human volunteers. The use of mentally handicapped children and prisoners in such studies has been criticized on many occasions and the background and justification for such studies were recently summarized by S. Krugman and J. P. Giles (*J. Amer. Med. Ass.*, **212**, 1019; 1970). Apart from the ethical issues involved, however, several questions are inevitably raised by these studies. First, it is known that although the MS-2 serum contains Australia antigen this serum gives rise to a mild and now well characterized form of serum hepatitis. Second, the agent of serum hepatitis has not been finally characterized and the injection of heated and diluted whole serum containing Australia antigen is rather a crude way of inducing immunity. The serum may, of course, be regarded as an inactivated "vaccine", but some purified inactivated vaccines such as measles and respiratory syncytial virus have sensitized rather than protected the recipients. In terms of hepatitis this is an important problem because several workers have suggested that there are similarities between Australia antigen-associated hepatitis and type 3 hypersensitivity reactions in which the severity of the disease may depend on the balance between antigen and antibody (see review by A. J. Zuckerman, *Bull. Wld Hlth Org.*, **42**, 957; 1970). Finally, active immunization against serum hepatitis is likely to have only limited application, for example to children and adults in crowded institutions such as hospitals for the mentally handicapped and more so to certain groups at high risk to hepatitis such as patients and staff of renal dialysis units, transplant surgeons and perhaps some laboratory workers. The problem of active immunization against the much commoner epidemic form of hepatitis remains elusive.

APHIDS

A Sticky End

SOME species of wild potato seem to have a most effective mechanism for resisting attack by aphids—the glandular hairs on the leaves and stems discharge a gummy substance when damaged by the tarsi of an aphid; this exudate first of all restricts the insect's movements and further accumulations lead to the complete immobilization of the aphid and to its death. This mechanism is described by Dr R. W. Gibson of Long Ashton Research Station, Bristol, who has been experimenting with three species of wild potato, *Solanum polyadenium*, *S. tarijense* and *S. berthaultii*, and two aphid species, *Myzus persicae* and *Macrosiphum euphorbiae* (*Ann. Appl. Biol.*, **68**, 113; 1971).

In the three species of wild potato examined, the gummy exudate is produced from the tip of the glandular hair when an aphid mechanically ruptures the cell walls. In the intact hair, this substance seems to be a clear, water soluble liquid but on contact with air it changes to a dark brown or black insoluble sticky substance which is deposited on the aphid's limbs. Gibson found that not every contact of an aphid with a glandular hair resulted in the release of the exudate, but about 30 per cent of the aphids placed on any of the three species of wild potato became stuck to the plants by the substance within 24 hours. Starvation was probably the final cause of death; Gibson also noticed that the gummy substance occasionally found its way on to the labium of an aphid and this may also have prevented the aphids in his experiments from feeding.



Glandular hair on *Solanum berthaultii* of the type consisting of a four-celled head mounted on a stalk.

Although Gibson observed a wide variety of hairs on the leaves and stems of the three wild potatoes, the type with the four-lobed head (see figure) mounted on a stalk seems to be the principal, if not the only, source of the gummy material. These hairs are abundant on

Turning a Corner in Nucleic Acid Structural Studies

IN many ribonucleic acids, double helical base-paired regions are formed by a single polynucleotide chain folding back on itself. It is usually (and not unreasonably) assumed that these double helical regions have a structure similar to that determined by X-ray crystallography for the completely double helical molecules of reo virus and wound tumour virus RNA. But there have been no such impeccable guidelines for the conformation of the single stranded loops at the end of each double helix. Many of these loops, such as that containing the anticodon in transfer RNA, can be expected to have important roles in biological function and information on their structure is unquestionably of great significance. No doubt much will be revealed when the first single crystal analysis of a transfer RNA molecule is achieved. This happy event, however, still seems a little way off. In the interim attention has turned to the problem of turning a corner along a polynucleotide chain.

The information comes from the determination by Seeman *et al.* (see next Wednesday's *Nature New Biology*) of the crystal structure of the naturally occurring dinucleoside phosphate, uridine 3′, 5′ adenosine phosphate (UpA). There are, in fact, two molecules of the dinucleotide in each asymmetric unit in this crystal, thus providing at some modest additional effort to the authors two independent determinations of the structure of UpA. Although these two molecules have quite different overall conformations, Seeman *et al.* point out that these are attributable primarily to differences in orientation about only two single bonds—the two successive P-O bonds along the dinucleoside chain. The orientations found in one of the molecules are such that a polynucleotide chain containing a dinucleoside with such a conformation would turn a corner—actually through 180° in the space of one phospho-diester link. This structure observed for UpA seems to represent a particularly neat solution for the production of a sharp bend in a polynucleotide chain and it would be surprising if use is not made of this stereochemical possibility of some close variant of it in studies of the biological function of nucleic acid.

The interbase hydrogen bonding in UpA is also of considerable interest. Although base pairing is common in crystals of bases, it is relatively rare in crystals of nucleosides and nucleotides where hydrogen bonding of the bases to water, sugar hydroxyls and charged phosphate oxygens is frequently observed. This is a point which many builders of transfer RNA models seem not to have realized, because in most models tertiary structure is attributed to base pairing between single stranded regions of the clover leaf. In this context the structure of UpA is an exception to the rule because it does have base pairing. This, however, is not complementary pairing in which adenine–uracil pairs of the Watson–Crick type hold together two molecules of UpA, but is self-pairing between uracils and also between adenines.

all three wild species examined—they reach their greatest density on the stems—but are very scarce in the cultivated potato, *Solanum tuberosum*.

Could this resistance mechanism in wild potatoes be bred into the cultivated potato? Gibson provides no hint of the practical problems involved, but suggests that in theory this form of resistance in a strain could combine very successfully with resistance based on mechanisms which increase the restlessness of the aphids.

OCEANOGRAPHY

Changing Chemistry

from a Correspondent

IN connexion with the celebration of the 350th anniversary of the founding of Göteborg, the Nobel Foundation agreed to hold a symposium (the twentieth in the series) on the theme of the changing chemistry of the oceans with particular reference to the influence of man on the marine environment. This meeting took place at Aspenäsgarden near Göteborg on August 15–20.

The opening address was given by Professor Arne Tiselius (University of Uppsala), chairman of the Nobel Committee for Chemistry, and a Nobel prizewinner. He stressed the importance of marine science and requested that the delegates draw up a series of resolutions on aspects of marine pollution to be submitted for consideration at the United Nations conference on the human environment to be held in Stockholm next year.

Although many of the formal contributions, and much of the subsequent discussion, did revolve around various aspects of marine pollution, purely academic concepts were not neglected. The overall scope of the symposium included world-wide atmospheric and oceanic circulation patterns and their variability, trace gases in both the atmosphere and sea water, the chemistry of marine aerosols and surface films, bacterial activity in the oceans, the control of energy cycles in the sea, the impact of man on the major sedimentary cycles, the atmospheric transport of material to the oceans and the budget of trace solubles in sea water. The case histories of certain pollutants, such as mercury, chlorinated hydrocarbons (DDT and PCBs), phosphorus and hydrogen sulphide received special consideration.

Dr J. Ui (University of Tokyo) spoke of the dangers to health which may arise from the release of mercury into the natural waters of a densely populated area. He illustrated his talk with a harrowing film showing victims of the "Minimata" disease which was caused by consumption of fish contaminated by methylmercury formed bacterially from inorganic mercury present in wastes discharged into Minimata Bay, Japan.

It was his opinion, which was endorsed by other speakers, that mercury pollution, terrible though its consequences are, is only likely to be a local problem, because the amount of mercury reaching the sea as a whole is only a small fraction of that entering by geological processes. He considered that a much greater threat is posed by toxic chlorinated hydrocarbons such as DDT and polychlorinated biphenyls (PCBs) which enter the sea by way of the atmosphere, and are therefore distributed globally. These lipophilic compounds are concentrated by marine animals at many levels in the food chain.

Dr Ui's arguments were reinforced by analyses presented by Professor E. D. Goldberg (Scripps Institution of Oceanography) and Dr V. T. Bowen (Wood's Hole Oceanographic Institution) which showed that concentrations of the PCBs in marine animals from both the Pacific and the Atlantic were often many times higher than those of DDT; values as great as 300 p.p.b. (fresh weight) of PCBs have been recorded for zooplankton from the north Atlantic. It was suggested that concentrations of these chlorine-containing compounds are reaching the levels at which they may produce ecological effects, and that further increase may present a hazard to human health. It was the unanimous opinion of the symposium that restrictions on the use of these chemicals should be applied internationally.

Professor Goldberg discussed one of the most important concepts in contemporary environmental science—that man himself has now become an important geological force in his own right. He made a comparison between the fluxes of material introduced into the environment by man and those introduced by natural phenomena and concluded that man must now be considered a serious rival to nature.

Considerable time was spent on discussions about international measures which should be taken before it is too late to control and monitor the discharge of toxic, or potentially toxic, wastes into the sea. Emphasis was placed on the need for research into the ecological effects of the compounds concerned, and for studies of their routes through the marine food chain, and of the way in which they are degraded.

How *lac* Repressor Works

IN next Wednesday's *Nature New Biology*, Pastan and his colleagues report their latest manipulations of their cell free system which allows them to observe *in vitro* the regulated expression of the lactose operon (see *Nature New Biology*, **231**, 139; 1971). They have now focused their attention on the question of how the *lac* repressor prevents transcription, and have come to the conclusion that with the wild type *lac* operon the repressor does not prevent the actual binding of RNA polymerase to the promoter site but somehow prevents the bound polymerase from getting on with the job of transcription. But with a mutated *lac* operon, which carries a mutation in the promoter site that enhances the expression of the operon *in vitro* as well as *in vivo*, the repressor acts in part by preventing the binding of polymerase.

Pastan and his colleagues incubated wild type *lac* DNA with RNA polymerase in the presence of the cyclic AMP binding protein and cyclic AMP, which they believe somehow enhances the affinity of the polymerase for the promoter region. The polymerase as a result binds to the promoter and in the absence of repressor and the presence of the nucleoside triphosphates it can transcribe the operon. If, however, Pastan *et al.* incubate the DNA with repressor either before or after it is incubated with the polymerase, transcription is blocked. Moreover, if an inducer is added to the system, together with rifampicin to mop up any unbound polymerase, the repression is overcome and RNA is made. It is clear therefore that repressor and polymerase do not compete for the same binding site; each can bind independently of the other and the repressor must act by blocking a step after polymerase is bound. Wild type promoter and operator sites are thus not the same nor do they overlap.

When, however, Pastan *et al.* repeated these experiments with *lac* operon DNA carrying a promoter mutation, which enhances the expression of the operon, they found that the addition of repressor after polymerase had bound to the DNA only partially inhibited RNA synthesis. By contrast, when repressor is bound before polymerase is added repression is complete and there is no transcription. These and other observations lead Pastan and his associates to conclude that the polymerase and repressor partially compete for a site on this mutated DNA. They suggest that either the mutation has, by deletion, brought the wild type promoter and operator sites closer together or, and more likely perhaps, the mutation has generated a new promoter which is closer to the wild type operator site. It is clear, therefore, that the same repressor molecule can bring about repression in more than one way.

Mechanisms of Sound Localization

I. C. WHITFIELD

Neurocommunications Research Unit, University of Birmingham

In this shortened version of his Charnock Bradley Memorial Lecture delivered at the University of Edinburgh in November 1970, Dr Whitfield describes the mechanism whereby the differential intensity and time of arrival of a sound at the two ears allow the brain to determine the direction of arrival.

THEORIES of hearing have, from the earliest times, been overly concerned with frequency analysis, perhaps because of the classical interest in the relation between musical instruments and the physics of sound. Yet for survival in a hostile world, the role of the auditory system in identifying and locating the sounds made by friends and foes has undoubtedly been the more important one for most species. The early resonance ideas which concerned the cavities of the inner ear were indeed formulated more with the idea of providing an amplifying property than an analytic one, but as early as 1683 the Paris physician du Verney[1] proposed a resonance theory of frequency analysis, antedating Helmholtz by at least 150 years.

Theories of sound localization seem to have developed much later. Boring[2] has suggested that this was due to the philosophical climate of the early nineteenth century, which found the concept of auditory space difficult. Because of the ample evidence that the blind, for example, can find their way around using auditory cues, attempts to circumvent the difficulties induced by this philosophy were made by invoking tactile mechanisms as an explanation for sound localization.

By the middle of the century, experiment was beginning to take over, and with it the recognition that localization of sound depends on the differences between the stimulus conditions at the two ears[3]. An early attempt to control these differences was made by Alison[4], who in 1858 described experiments with a "differential stethophone" which could be used to lead sound from a common source independently to the two ears. He showed that if the sound was louder in one ear than the other, then all the sound seemed to be in that ear, irrespective of the actual situation of the source. He interpreted his results as supporting the idea that localization depends on an intensity difference between the two ears.

The philosopher Alexander Bain, writing in 1855 (ref. 5), had to admit that the possession of two ears played some role in localization, but still insisted that this was very crude and that sound localization depended largely on "experience".

The work of the next hundred years was principally devoted to validating the importance of binaural phenomena and to demonstrating their accuracy; yet there is now reason to believe that past experience in the interpretation of auditory signals may well play some part in localization, though hardly to the extent which Bain supposed.

Rayleigh[6] in 1877 investigated very thoroughly the localization of tones produced by tuning forks and firmly established that intensity difference was a powerful factor in assessing the direction of a sound source. He realized, of course, that although these differences in intensity could be produced at high frequencies (short wavelength) by the shadowing effect of the head, it was difficult to account (in the absence of head movement) for our ability to localize low frequencies where shadowing is negligible. He thought that phase might play a part, and investigated this possibility by leading the sounds of two slowly beating tuning forks into the two ears through long tubes. He was unable to get any impression of movement of a sound image as the phases slowly changed and so rejected the idea. It was not until some thirty years later[7] that he returned to the problem; he then reported that if the experiment were performed with the ends of the tubes separated from his ears by a short distance—instead of having the tubes actually in his ears—the impression of directional change was very definite.

In 1908 Mallock[8] studied the apparent direction of the sound of rifle fire when he stood at different positions close to the line of fire. He found that not only was the apparent direction of the sound source not that of the rifle itself, but that the position of the source varied with the position of the observer along the line from gun to target. He concluded that what he was localizing was the shock wave of the bullet, and that this localization depended on the differential time of arrival of the crack at the two ears. This seems to have been the first study of the influence of a pure time difference in localization rather than a phase difference.

The First World War stimulated much experimentation in sound localization, and the development of electronic methods in acoustics in the 1920s and 1930s extended and elaborated the studies without adding anything substantially new. Study of the physiological mechanisms involved had to await a further stage in electronic development and these date from the late 1940s onwards. Many of the mechanisms are, indeed, still not understood.

Phylogenetic Development

In looking at what little is known, it is best perhaps to start with a look at the internal ear. It is now well known that a sound (say a single tone) sets up a travelling wave along the basilar membrane which passes from the basal to the apical end, reaching a maximum amplitude at some point and then rapidly dying out. The distance it travels before peaking and dying out depends on the frequency—the lower the frequency the further along the cochlea is this point. If a click with a sharp leading edge is used as a stimulus, then the higher frequencies are gradually filtered out as the wave travels along and only the lowest components arrive at the apex.

During phylogenetic development of the ear, the basilar membrane seems to have become progressively elongated. It is less than 1 mm long in reptiles, 5 to 10 mm long in birds and 20 to 30 mm long in mammals. Parallel with this there seems to have been an increase in the high frequency response. Reptiles (and fishes) respond only up to 1 or 2 kHz, birds reach 5 to 10 kHz, but among mammals the response of the guinea pig extends to about 40 kHz and that of the cat to 70 kHz. Man is, of course, a rather poor mammal with an upper limit of 20 kHz. This extension of the high frequency response is of interest because of the importance of high frequencies for localization mechanisms.

The input data for the central nervous system—on the basis of which the source must be located—consist, of course, of impulses in the auditory nerves, and these impulses are in turn generated by mechanical movements of the hair cells induced by vibration of the cochlear partition of which they form a part. It seems that when the hairs of the hair cells are flexed in one direction there is an increased tendency for impulses to be initiated in the associated nerve, and a correspondingly reduced tendency for impulse initiation when they are flexed in the opposite direction. Certainly there is abundant evidence that nerve impulses tend to be discharged at a particular phase of a stimulating sinusoid[9], and we can see at once that the time difference hypothesis and the phase difference hypothesis are—as far as the nerve is concerned—much the same thing. We have presumably to look for some central nervous mechanism which can assess the time disparity (Δt) between corresponding impulses in the two auditory nerves. It is not, however, quite as simple as that because an action potential lasts about 1 ms and the maximum delay between the arrival of a click at the two ears, even in humans, is about 700 µs; in an animal such as the cat the delay is closer to 200 µs. We can in fact deal with delays much less than this, such as those which occur when the sound is only a little off centre. Experiments performed by delivering clicks through headphones to the two ears separately indicate that delays of 40 to 50 µs give an off-centre image. What is the mechanism? If we look at the rate of propagation of the travelling wave along the membrane we see that near the base it is travelling very rapidly[10]. To reach a point about 7 mm from the base takes only a few microseconds (this represents a position responding maximally to about 4 to 5 kHz). If we stimulate with a click containing high frequency components, then there is a barrage of impulses in the auditory nerve fibre array (several thousand fibres), which gives a statistical picture of the time of onset. For lower frequency pure tones we would expect localization to be worse, and this is, in fact, the case.

Comparing Information

How does the central nervous system deal with this time disparity information? Clearly, the information in the two auditory nerves has to be compared, and the first point, anatomically, at which this can happen is the superior olive, which receives connexions from both sides. The medial olivary nucleus has a remarkable structure; it consists[11] of bipolar cells with oppositely directed dendrites. The auditory input from one side makes contact with one set of these dendrites and that from the opposite side with the other set. The whole configuration is, of course, symmetrical with respect to the two sides of the brain stem. A number of workers, notably Hall[12], have recorded outputs from these cells while stimulating the two ears with paired clicks. The probability of a cell firing is found to be a function of the time disparity between the two signals. If the contralateral click is leading then the probability of a response is higher than if the ipsilateral click is leading; increasing the intensity of the clicks also raises the probability, of course. There are, however, two of these nuclei, one on each side, and we find that the ratio of the firing probabilities on the two sides is independent of the absolute intensity level. A difference of intensity between the two sides will affect this ratio, but this actually enhances the effect because the sound in the leading ear would normally be louder than that in the trailing ear if the stimuli came from a real single source.

The problem thus seems to be solved; some higher level of the nervous system has simply to assess the comparative outputs of the two medial olivary nuclei which vary with both time and intensity. When cats, for example, are deprived of both auditory cortices, they cannot localize sound (though they can respond to it—they are not deaf[13]); we note, too, that there are nerve cells in the cortex which respond only when the sound is on one side of the animal's head and not at all when it is on the other[14]. If we postulate that these are the cells which are (directly or indirectly) "looking at" the differential olivary output, it seems superficially as if we may have identified the mechanism. Again, however, there are difficulties.

The relative development of the nuclei of the olivary complex varies considerably from species to species[15]. Some animals—the bat, the hedgehog, the dolphin—apparently have no medial olive, whereas the cat and the dog have the medial and lateral olivary nuclei about equally developed. In monkeys and man it is the medial olive which predominates, though in no species is the lateral nucleus entirely absent. It is interesting that these differences are reflected in nomenclature; in the cat it is the medial nucleus which anatomists have labelled the accessory nucleus, but in man it is the lateral nucleus which is so named. It is tempting to note the apparent correlation of these histological differences with head size; a medial olive is associated with a large head size, for which Δt would be large, and not with a small head size, for which Δt would be smaller. Before coming to any conclusions, however, we must recall that more "visual" species have larger medial olives than less visual ones.

Masterton, Jane and Diamond[16] trained cats to distinguish between clicks presented by earphones to the right ear and to the left ear. They then presented the animals with paired clicks (right–left (RL) or left–right(LR)) in which one preceded the other by 500 µs. As expected, they found that a normal cat treats RL just like a single click on the right and LR like a single click on the left. They then divided the trapezoid body so that the cross-connexions between the two accessory olives were severed. The animals could no longer solve the RL and LR problem. They could, however, still solve the L v R problem, so that relative intensity cues were evidently available by a different route. The experimenters further showed that partial lesions of the lateral lemniscus were capable of dissociating the two paths so that the L v R problem and the LR v RL problem were no longer treated as equivalent, that is both problems could be learned but there was no transfer.

Localization and the Pinna

We thus see that the time/intensity analysis of the accessory olive is not the sole mechanism of localization. Indeed when we come to look at the matter more carefully we see that time is a very ambiguous clue. There are in fact complete surfaces (hyperbolae of revolution) with the same time delays. Because of the irregular head shape and the existence of the pinnae, however, the relative frequency attenuation varies greatly with the orientation of the source. Thus the waveform at one ear is quite different from that at the other ear if the sound is complex (as it usually is) and this difference may be unique for each position. Batteau[17,18] conducted many experiments on the role of the pinna in localization and showed how the received sound varies as the direction of the source is changed. Indeed this gives some indication of how we can locate sound even with one ear, though not very accurately. Such localization is, of course, not mechanical but depends on learning the patterns from past experience, just as we learn visual distance judgment from such things as atmospheric colour filtering. That there is some physical basis for the proposal is shown by the observation that artificial pinnae on microphones can be used to transmit the effect to a subject through earphones.

Now Rayleigh observed that when he had tubes in his ears leading in sounds he had no impression of direction, whereas when the ends of the tubes were an inch or so away he got the impression of direction very definitely. No doubt this is an example of the psychological effect of one clue cancelling the effect of another. If we perform on ourselves the experiment of delivering to our own ears through headphones clicks which are disparate in time—as in the experiments with the cat—we find that as the interval is altered, the sound certainly moves, but is lateralized rather than localized, that is to say it moves from side to side either inside your head or very close to it; it is not located out in space as is the case for a real source. It seems that the frequency spectrum distortion provided by the head and pinnae is an important factor in this effect. But it may not be a complete explanation because Toole[19] has recently shown that even real external sources in an anaechoic chamber may in certain circumstances produce images inside the head.

There is, indeed, another factor in localization which we have not yet considered, and which may in normal circumstances contribute to the exteriorization of the source. So far we have been regarding a sound as two signals reaching the two ears at two points in time. This may be true in a large flat unpopulated open space, but in most circumstances these signals are accompanied by later versions reflected from surrounding objects. As sound travels roughly one foot in one millisecond, the sound of a voice reflected from a room wall may reach the listener five to ten milliseconds later, and there are many of these reflexions. Of course we do not hear them separately, and all the sound appears to come from the primary source. It it not that the reflexions are suppressed; they add to the total loudness, so that one must speak much more loudly in the open air than in a room. This phenomenon is known as the precedence effect[20], and is used commercially in sound reinforcing systems. The difficulty of situating a public address loudspeaker near the person talking is that it feeds back into the microphone and causes a howl. If, however, the speech fed to the loudspeakers is delayed so that their sound reaches the ear a few milliseconds later than the direct voice then the loudspeakers can be placed near the audience at the back of the hall and yet all the sound appears to come from the direction of the speaker's mouth.

With a single source on the left, the sound reaches the right ear about 0.5 ms later than the left ear, If, however, there is a reflector 3 feet away on the right, a second sound will arrive at the right ear 6 ms later and at the left ear 6.5 ms later. The auditory nerves will certainly respond to all four signals and indeed they can be traced in gross responses right through the auditory pathway, though the second response may be rather smaller than the first. Although, as we have seen, the second signal pair adds to the intensity of the whole and even to the intelligibility of speech, it is nevertheless the first signal pair which predominantly determines the apparent location.

Function of the Cortex

We have recently[21,22] been investigating the role of the cortex in this phenomenon, as it seemed that the cortex played an important role in "out-thereness". First, we trained cats to go to a food box on the left when a loudspeaker behind that box was delivering a train of five tone pulses per second, and conversely to go to a food box on the right when a similar train of tone pulses came from a speaker on the right. In other words, they were trained to "go to" the sound. It is known from the experiments of Neff[13] that a cat with no auditory cortex cannot do this but, provided either the right or the left auditory area is intact, the animal can perform the discrimination just like a normal animal.

If we intersperse among these real rights and lefts some compound rights and lefts made by having the right pulse precede the left by 5 ms or vice versa, normal cats will treat these exactly as if they were real rights or lefts—they "transfer" immediately without further training. This, of course, is just what we would expect from the precedence effect we have been discussing. If, however, we take out one auditory cortex a difference emerges. We removed the right auditory cortex from half of the animals and the left auditory cortex from the other half. After the operation both sets of animals made no mistakes about stimuli from the right or left: we did not expect them to. But there is a clear difference between the response of the two groups to the compound stimuli (RL or LR). The right lesion cats perform correctly on a compound right (RL) but fail on a compound left (LR), whereas the left lesion cats can do the compound left but fail on the compound right. In other words, the contralateral auditory cortex seems essential for the correct interpretation of these compound signals. Some light on what actually occurs is given by other experiments in which uni-decorticate cats were trained to go left to a signal on the left, but to go right when signals were present on both right and left speakers without any fixed temporal relationship (to avoid the precedence effect the two trains were unsynchronized so that the left/right interval varied continuously). When these animals are exposed to compound signals the left lesion animals appear to be normal, they go left to a compound left (LR) and right to a compound right (RL) signal. But the right lesion cats go to the right whichever stimulus (LR or RL) occurs. With reversal training in which the animals are trained to go right to a single stimulus and left to the double stimulus it can be shown that the left lesion cats are not, in fact, normal, as they now break down and tend to go left to both RL and LR. These results suggest that it is the temporal order of the pair of stimuli which is lost when the cortex contralateral to the earlier member of the pair is damaged.

These observations may explain the difficulty which humans with one sided temporal lobe damage are reported to have in localizing sounds on the side contralateral to the damage, while having no difficulty with sounds on the ipsilateral side. Possibly the precedence effect breaks down in these circumstances, and reflexions cause confusion.

There are evidently comparatively simple and well understood mechanisms at the level of the brain stem which are capable of using the clues of differential intensity and differential time of arrival of a sound at the two ears to compute the direction from which it arrives, just as a range finder might. Some ambiguities in the result can obviously be resolved by moving the receivers (head movement) in the sound field, but only if the sound is repeated or continuous. In any real situation ambiguities arise not only because more than one position of the source can give rise to the same time differences but because of multiple reflexions. In the resolution of these ambiguities, the cortex seems to play an essential role, as it does in the assignment of position as well as direction to a source (what I have called "out-thereness"). It could well be asked whether "out-thereness" has any meaning except in so far as we are able to collate the auditory input at a cortical level with our motor experience of exploring the world around us.

Effect of Earthquakes on Deep-sea Sediments

T. J. G. FRANCIS
Institute of Geological Sciences, UKAEA Blacknest, Brimpton, Reading, Berkshire

It is suggested that sediments filling the oceanic trenches and transform faults suffer periodic liquefaction by earthquakes. Such a phenomenon could explain the presence of undeformed turbidite beds in highly tectonic zones and make them an ideal site for toxic waste disposal.

GEOLOGICAL and geophysical evidence from the mid-oceanic ridges generally supports the concepts of plate tectonics, but the interpretation of evidence from the areas where plates are colliding is much more obscure[1-9]. One baffling problem is the almost complete lack of deformation in the sediments found in oceanic trenches[10,11], the "sinks" of plate theory, where one plate is under-thrusting another and being consumed into the mantle. Relative motion between colliding plates may be several centimetres per year[8], and the boundary between them is marked by a steeply dipping earthquake zone, the Benioff zone, extending as much as 700 km into the mantle[12,13].

Several seismic reflexion profiles have now been made of the sediments filling oceanic trenches (Fig. 1), but there is no evidence for the accumulations of contorted sediments that were originally expected[10,11]. One possibility is that crumpled sediments lie beneath the overlying undeformed fill, but cannot be detected because the latter is acoustically absorptive[14]. But beneath flat-lying turbidite beds Scholl *et al.* have identified oceanic pelagic sediment, very similar in thickness and acoustic properties to that exposed to seaward of the trench and beneath that a rather well defined basement. What evidence there is for chaotic reflexion hyperbolae at the base of the continental slope in active trenches[15] can be explained by reflexions from sediments which have slumped down the continental slope[16] or from harder rock features of the slope itself. The two plates shown in Fig. 1 are moving together at about 6 cm yr^{-1} (ref. 8) and, if the oceanic plate is carrying the trench sediments along on its back like a conveyor belt, a column of sediment approximately 1 km thick is constantly being pushed up against the continental slope. In a million years 60 km of such a column—more sediment than is visible in the whole of Fig. 1—must be disposed of. It is difficult to believe that any geological process can do this so efficiently that what is left can hardly be observed on a seismic reflexion record.

But it has always been assumed that the trench sediment is behaving as a plastic solid, displaying much the same mechanical properties as those of a sediment core resting on the laboratory bench. The static and dynamic physical properties of unconsolidated sediments are, however, seldom the same. In particular many unconsolidated sediments display the phenomenon of thixotropy, whereby a body changes from a semi-solid, jelly-like state ("gel") to a liquid state ("sol") on being shaken and reverts back to the jelly-like state on standing. Thixotropic behaviour by the sediments filling oceanic trenches under the influence of earthquake vibrations could account for their lack of deformation.

Vibrational Environment of Epicentral Zone

Such vibrations could originate in the Benioff seismic zone, which crops out along the inner margin of oceanic trenches[12,13]. It is certain that much of the relative movement between colliding plates is accompanied by seismic activity. But fault movement can occur without earthquakes. For example, some sections of the San Andreas fault, separating the North Pacific and American plates, move with "fault creep", whereas others seem to be "locked" and strain is relieved by infrequent but severe earthquakes[17]. The locked stretches are thought to be the result of the curvature of the fault, that is, of increased forces holding the plates together. Because the Benioff zone involves underthrusting rather than strike-slip faulting, the forces normal to the zone must in general be greater than in the case of a transform fault. Thus the shallow faults of a

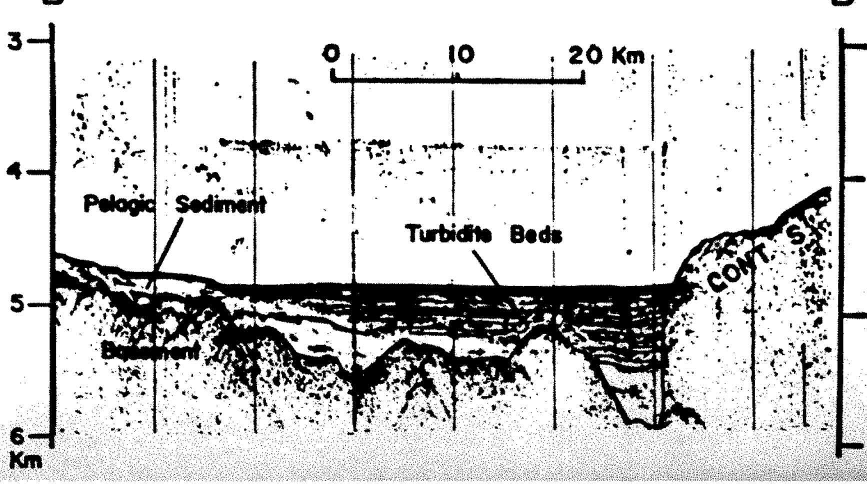

Fig. 1 Seismic reflexion profile taken by Scholl, van Huene and Ridlon[11] across the Peru–Chile trench, showing undeformed turbidite fill.

Benioff zone are probably of the locked variety. It seems plausible to conclude therefore that most, if not all, the relative movement between colliding plates is accompanied by earthquakes.

It is generally agreed that shallow earthquakes are produced by relative motion of the two sides of a fault surface[18]. Relative motion initiates at some point on the fault surface, then spreads outward on that surface at a finite velocity. Rupture velocities determined theoretically and experimentally give figures somewhat less than the shear velocity, or roughly half the compressional velocity, of the faulting material[18-22]. Thus P and S waves from the initial rupture will precede the active faulting everywhere except where it is initiated. At 5 km from the initial point, typical crustal rocks would experience approximately 1 s of vibration before the rupture starts. Near the source the vibration contains much high frequency energy (say, 2–100 Hz), most of which is attenuated by teleseismic distances. Moreover, the point at which rupturing starts is unlikely to be at the Earth's surface. Even where shallow earthquakes have resulted in surface faulting, it is usually thought that faulting started at some depth, possibly several kilometres[23]. Thus the hard rock surface at the epicentre itself will usually experience at least a second of vibration before any faulting arrives.

During the Parkfield, California, earthquake of June 1966 an array of accelerographs was in operation across the part of the San Andreas fault which ruptured[22-25]. The earthquake had a Richter magnitude of 5.6 and the USCGS reported $m_b = 5.3$. The fault ruptured over a length of 30 km, the rupture initiating at a depth of about 5 km. Surface faulting was visible over a similar distance to the fault length inferred from Love Wave spectra, but offsets of the fault were only a few centimetres. A maximum acceleration of $0.5g$ was recorded 200 feet from the fault trace, falling to about $0.1g$ at a distance of 15 km[24,25]. Much of the energy recorded in the accelerograms was at periods less than 1 s, and the shaking lasted for a few seconds. Although this earthquake is different in many respects from those occurring just beneath the ocean floor on the Benioff zone, these figures give a general idea of what to expect there from an earthquake of similar magnitude.

Housner[26] has shown that maximum ground accelerations decrease with distance from the fault, but that the rate of decrease is small over distances comparable with the dimensions of the fault. An earthquake such as the Parkfield one subjects a ground area of a few hundred square miles to maximum accelerations of more than $0.1g$. A major earthquake with Richter magnitude 7.5 would subject an area of no less than 14,000 square miles to such accelerations, and an area of 2,000 square miles to maximum accelerations of more than $0.3g$. The duration of strong shaking can exceed half a minute for major events.

Thixotropy of Unconsolidated Sediments

Boswell[27] has shown that, except for coarse clean sands and gravels, all unconsolidated sediments are thixotropic to some degree, and that thixotropy is augmented by an increase in the proportion of finely divided particles and of platy or acicular grains as compared with equidimensional particles. It is also usually increased by the presence of electrolytes such as those present in seawater as opposed to freshwater. Boswell found many sands to be thixotropic at porosities between 35% and 50%, muds and clays at porosities between 50% and 70%. The actual porosity range over which a given sediment exhibited thixotropy varied from a few per cent to 20%. Expressed in terms of the Atterberg limits of soil mechanics, all unconsolidated sediments are likely to be thixotropic near the liquid limit; the question is how far the thixotropic properties extend towards the plastic limit. Even at larger water contents than the liquid limit, thixotropy may be important in reducing the viscosity of sediment slurries.

Freundlich and Juliusburger have shown that thixotropy can account for some quicksands[28]. In particular, they demonstrated that a quicksand from Knott End, Fleetwood, was thixotropic due to the presence of only 2.1% of fine clay. Separation of the clay fraction suppressed the thixotropic behaviour, but it reappeared on remixing the clay with the residue. Sands neighbouring the quicksand contained only 0.3% clay and were not thixotropic.

In physical terms, thixotropy occurs when particles form a loosely packed "house-of-cards" structure[27-30]. Shearing stresses break the contacts between particles and thixotropy arises because time is required for the structure to reform. Particle shape is important because isometric particles tend to form close-packed structures whereas platy and acicular ones form open structures. Factors such as the concentration of electrolytes (affecting the electrostatic repulsive forces between particles) and the viscosity of the pore fluid are important because they control the time required for the structure to reform.

Physical Properties of Deep-sea Sediments

High porosity is perhaps the most striking characteristic of the unconsolidated sediments of the ocean floor[31,32]. Porosities in the region of 70% are the rule and only rarely does the presence of an increased sand fraction reduce the porosity below 60%. The pelagic sediments of abyssal hills and the clayey silts and silty clays of abyssal plain turbidites all have porosities in the region of 80%. Furthermore, porosity decreases slowly with depth. At the Preliminary Mohole site it fell only 5% over 168 m (ref. 33). The sound velocity gradient in unconsolidated sediments and the well established relationships between sound velocity and sediment porosity provide an indirect means of inferring porosity at depth. One can conclude that even at depths of 1 km below the ocean floor, the porosity of unconsolidated silt-clay sediments is probably in the region of 50%. The fact that high porosity extends to depth implies that a house-of-cards type of structure does also, with only gradual orientation of the sediment particles towards the structure of laminated siltstone or shale.

Porosity alone, however, is not a reliable guide to either the strength of an unconsolidated sediment or its closeness to the liquid limit. In general, the shear strength of deep-sea sediments is low, but the strength of sediments of similar porosity may vary by a factor of a hundred or more[32,34]. Hamilton has pointed out that both very high and very low rates of accumulation can lead to sediments with little decrease of porosity with depth[33]. When the rate of accumulation is very high, the sediment layer is thick and very weak, but has not had time to consolidate under its own overburden pressure[35]. When the rate of accumulation is very low (say, < 1 cm per 1,000 yr), the contacts between sediment particles are firmly cemented before the overburden pressure becomes appreciable. The house-of-cards structure is thus transformed into a welded three-dimensional network capable of supporting a considerable overburden and giving the sediment appreciable strength. This is the explanation given for the surprisingly high strength of the sediments from the Preliminary Mohole[33,36], and is probably generally true of deep-sea pelagic sediments.

Thus the properties of many sediments on the ocean floor are such that, given the right vibrational environment, thixotropy is likely to be an important phenomenon. Rapidly deposited turbidite beds are more likely to display thixotropy than slowly deposited pelagic clays. No quantitative information is available on the level of vibration needed to induce thixotropy, but there is a great deal of evidence that the strong motion of earthquakes is sufficient to disturb the inter-particle relationships of unconsolidated sediments.

Effects of Earthquake Strong Motion

Liquefaction of saturated, cohesionless sands and silts has been reported in several earthquakes[37], but the mechanism of

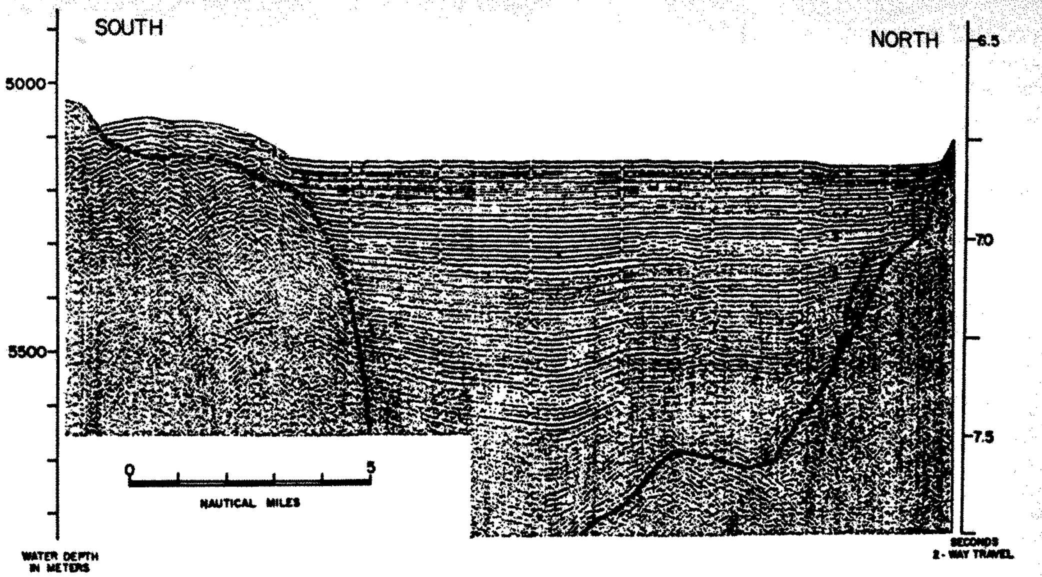

Fig. 2 Seismic reflexion profile taken by Van Andel, Corliss and Bowen[45] across the Vema Fracture valley, showing undeformed horizontally bedded sediments.

liquefaction when this occurs on land is generally thought to be moving pore water rather than thixotropy. Earthquake vibrations tend to shake cohesionless sands and silts into a more close-packed structure and thus increase the pore water pressure. The pore water flows upwards towards the surface and brings about liquefaction. The much smaller grain size of deep-sea sediment makes this mechanism less likely than thixotropy on the ocean floor, but the fact that it has been observed to have taken place on land demonstrates that the strong motion of earthquakes does disrupt the inter-particle relationships of unconsolidated sediments.

It is now well established that earthquakes provide a common triggering mechanism for submarine turbidity currents[38]. The classic example of this occurred off the Grand Banks of Newfoundland in 1929, when a magnitude 7.2 (Richter) earthquake[39] set a turbidity current in motion down the southern slope of the Banks. The velocity of the current has been inferred from the sequence of telegraph cable breaks[40] and its extent has been demonstrated by coring[41]. Sediment across 100–200 km of the continental slope was set in motion by this earthquake. The important point is that the level of earthquake vibration was sufficient to disturb the inter-particle relationships of the unconsolidated sediment throughout the epicentral area.

Liquefaction of Sediments in Oceanic Trenches

The various threads of the argument can now be drawn together to explain the absence of deformation observed in the sediments of oceanic trenches.

Throughout their existence, the turbidite beds of oceanic trenches will have experienced an unusual environment for marine sediments. Disturbed by the strong vibrations of frequent earthquakes, their inter-particle relationships will not have been static. Liquefaction, probably brought about by the phenomenon of thixotropy, will have periodically broken the contacts between particles and prevented their becoming permanently cemented.

In contrast, the pelagic sediments, approaching the trench on the oceanic plate, will have already acquired considerable strength as a result of inter-particle cementing before they reach the earthquake zone. The vibrational environment could therefore liquefy the turbidite beds but is unlikely to have such a drastic effect on the bulk of the pelagic sediments. Furthermore, since the initial ruptures of earthquakes generally lie at least a few kilometres below the base of the sediments, liquefaction of sedimentary formations could already occur before the appearance of faulting in the basement surface.

The brief and intermittent earthquake movements cannot impose shear stresses on the liquefied body of sediment and the latter will be effectively decoupled from the oceanic conveyor, just as the sea itself is. The situation is comparable with that of a bowl of water given a sharp tilt. The bowl moves, but the water level remains the same. Similarly the liquefied sedimentary pond in the trench retains its level and horizontal stratification as the oceanic plate slips by beneath. Moreover, although the cumulative movement of the oceanic plate, towards and underneath the continental plate, is quite rapid in geological terms, the actual shape of the sedimentary trap of the trench probably retains a rough dynamic equilibrium. Over a long period of time, several tens of millions of years, the relative velocities between plates will change and trenches come and go, But over a shorter time term, up to a few tens of millions of years, the relative velocities between the plates are probably quite constant. The general position of trenches would not vary although local adjustments of depth might occur. This might give rise to liquefied sediment redistributing itself along the trench. Such flows would not alter the character of the trench fill, but rather would tend to maintain its horizontal stratification and low strength.

Liquefaction of Sediments along Transform Faults

Besides the island arc/trench systems, the other prominent submarine earthquake zone follows the axis of the mid-oceanic ridges[42]. In general, of course, the crest of the mid-oceanic ridge is such a new feature that no appreciable sedimentary cover exists[43], but some fracture zones form troughs deep and extensive enough to trap turbidite sediments originating well away from the ridge itself. The Vema Fracture zone[44–47] in the equatorial Atlantic offsets the mid-Atlantic ridge by more than 300 km, is the locus of earthquake epicentres, and is filled by more than 1 km of horizontally stratified sediments, predominantly turbidites from the Demerara abyssal plain (Fig. 2). Interpretation of magnetic anomalies indicates that the north and south walls of the Vema transform fault are moving past each other at 2.8 cm yr^{-1} or, expressed differently, that the basement on the south side of the profile shown in Fig. 2 is about 20 million years older than that on the north side[7]. Nevertheless, the sedimentary fill observed is essentially undeformed.

Van Andel *et al.* originally interpreted the lack of deformation in the sediments of the Vema Fracture to indicate a long period of tectonic tranquillity, but were still convinced of the tectonic nature of the walls of the fracture[45]. A recent JOIDES drill hole coinciding with the profile of Fig. 2 has established an exceptionally high sedimentation rate in the Vema Fracture Valley, of the order of 1 m every 10^3 yr[47]. Even this rate, however, is but a small fraction of the rate at which the north and south walls of the transform fault are moving past each other and rapid sedimentation alone cannot account for the lack of deformation. Again the answer may lie in the effect of earthquakes on the physical properties of the sediment itself. The sediments filling the Vema Fracture have been shown to be rapidly deposited turbidites and consequently liable to thixotropy. Provided that movement on the Vema transform fault is largely seismic, the sedimentary fill in the fracture will be liquefied during movement of the walls and consequently will escape deformation and retain its horizontal stratification. It is quite reasonable to suppose that the largest earthquakes on the transform fault produce faulting throughout its 300 km length. In such an event the whole sedimentary fill of the transform part of the fracture and for many kilometres on either side would be liquefied.

Conclusions and Consequences

On a geological timescale liquefaction will be a frequent but transient occurrence, at any particular place averaging the order of seconds per year. Several months may go by without liquefaction, and at much longer intervals very large earthquakes will induce it for half a minute or more—a period comparable with their duration of strong shaking. Liquefaction implies a reduction in the viscosity of the sediment from that of a plastic solid (say, 10^4 poise) to that of a thick soupy liquid (say, 10 poise) and the loss of the plastic solid's yield strength.

Bostrom and Sherif have recently suggested that the tectonic sinks of the Earth's surface be used for waste disposal[48]. The occurrence of liquefaction in the turbidite beds of oceanic trenches would make this suggestion much more plausible. Furthermore, thickly sedimented transform fault valleys could be put to the same use. Waste material packaged to a density greater than that of the sediments would sink through the sediment whenever it liquefied. It is worth making an estimate of the rate at which a solid body would sink through the liquefied sediment.

Consider a sphere of diameter $d = 100$ cm and density $\rho_s = 3.0$ g cm^{-3} falling at a velocity U through a liquefied sediment of density $\rho_L = 1.5$ g cm^{-3} and viscosity $\nu = 10$ poise. The Reynolds number in such a case will be of the order of 10^3 so that the drag force the body experiences is independent of the viscosity of the liquid and is given by

$$F = \tfrac{1}{2} C_D U^2 S \rho_L$$

where S is the cross sectional area perpendicular to the direction of the motion and C_D is a dimensionless number called the drag coefficient. For a sphere $C_D \approx 0.4$ for Reynolds numbers in the range 10^3 to 10^5 (ref. 49). The terminal velocity of the sphere is given by

$$\frac{4}{3}\pi\left(\frac{d}{2}\right)^3 (\rho_s - \rho_L) g = \tfrac{1}{2} C_D U^2 \pi \left(\frac{d}{2}\right)^2 \rho_L$$

and therefore

$$U^2 = \frac{4}{3}\left(\frac{\rho_s - \rho_L}{\rho_L}\right)\frac{gd}{C_D}$$

Thus, with the values given, $U \approx 6$ m s^{-1}. Because the motion at these high Reynolds numbers is independent of the viscosity of the fluid, the velocity with which the sphere sinks through the sediment is only a factor of about $\sqrt{2}$ less than that at which it sinks through the sea. The duration of liquefaction has been tentatively estimated at s yr^{-1}, so that the average rate of sinking through the sediment of a body such as the sphere considered above might be about 20 m yr^{-1}. This rate far exceeds geological sedimentation rates and could be verified experimentally with simple apparatus in a few years.

That waste material dropped on the turbidite beds filling oceanic trenches and transform fault valleys would sink rapidly through the sediment is an attractive concept. Burial to a depth of a kilometre or more would occur in the human lifespan. As a site for the disposal of highly toxic chemical or radioactive wastes, the sedimented trenches and transform faults appear to be ideal. Such wastes have been dumped at sea for several years with remarkably little thought given to the consequences. Yet a major problem in the disposal of highly concentrated radioactive waste is the difficulty of ensuring that the package will last at least a few half-lives of the nuclides it contains. If natural geological processes exist which would allow such packages to bury themselves to a depth of a kilometre or so in sediment and this beneath seawater 5 km deep, such difficulties do not arise. A guaranteed lifetime of 50 yr for the package would suffice. And if leakage of the toxic waste then ensued, its effect even on the benthic environment would probably be undetectable.

I thank Dr H. I. S. Thirlaway and his colleagues for the facilities at Blacknest. This work was undertaken as part of the research programme of the Institute of Geological Sciences.

Murine Leukaemia Virus Group-specific Antigen in the C-Type Virus-containing Human Cell Line, ESP-1

RAYMOND V. GILDEN

Flow Laboratories, Inc., Rockville, Maryland 20852

WADE P. PARKS, ROBERT J. HUEBNER & GEORGE J. TODARO

National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20014

The C-type virus particle in ESP-1 cells seems to be a murine virus.

IDENTIFICATION and classification of non-cytopathic viruses isolated from human tissues or human cell cultures require a combination of morphological, biological, biochemical and immunological tests. Because of their characteristic budding appearance at the plasma membrane, C-type leukaemia–sarcoma viruses are usually identified by morphological criteria[1]. Further classification as to species of origin can be accomplished immunologically. Mouse, hamster, cat and rat C-type viruses each contain an internal virion protein, the group-specific (gs) protein[2] which carries species-specific antigenic determinants[3–5]. Thus, C-type viruses of these species can be identified specifically by a number of different immunological tests. C-type particles have been described in a human cell line, ESP-1, derived from a patient with lymphoma, and the results indicated that this putative human virus has none of the known gs antigens[6]. We describe here immunological studies showing that the ESP-1 cells contain an antigenic determinant identical to the species-specific antigenic determinant of murine C-type viruses.

The ESP-1 cell line was obtained at the forty-first passage level through the courtesy of Drs Elizabeth Priori and Leon Dmochowski (M. D. Anderson Hospital and Tumor Institute, Houston, Texas). The original cultures were received as monolayer cultures and maintained in two different laboratories throughout these studies. Extreme care was taken to avoid contact with other C-type virus-infected cell cultures: this included use of isolated work space and maintenance of flasks in incubators containing only ESP-1 cultures. Media consisted of McCoy's plus 20% foetal calf serum or RPMI 1640 plus 10% heat inactivated foetal calf serum. Although the ESP-1 cell line is contaminated with mycoplasma, no antibiotics other than penicillin and streptomycin were used.

To determine the immunological relationship of the C-type virus in ESP-1 cells with the known mammalian C-type viruses, complement-fixation (CF), radioimmunoprecipitin inhibition (RIPI), and gel diffusion studies were performed. The following reagents gave consistent positive reactions in CF tests with 10–20% v/v ESP-1 cell homogenates: eight serum pools from rats bearing murine sarcoma virus (MSV) induced tumours which were selected for reactivity with the mouse gs antigen[7] and serum from two rabbits and three guinea-pigs immunized with the purified[8] gs antigen of mouse C-type viruses (MuLV). In contrast, no CF reactivity was obtained with guinea-pig antiserum prepared against purified feline (FeLV)[4], rat (RaLV), or hamster (HaLV)[9] gs antigens. As Table 1 shows, concen-

Table 1 Reactivity of ESP-1 with Representative Antisera directed against Mammalian C-Type Viruses as detected by CF and RIPI

Sera *	Test	Antigen †	Antigen titre or range ‡
Rats with MSV-induced tumours	CF	MuLV	16– 64
		ESP-1	2– 8
Guinea-pig anti-murine gs	CF	MuLV	16–128
		ESP-1	2– 8
	RIPI	MuLV	250
		ESP-1	10
Guinea-pig anti-feline gs	CF	FeLV	64–128
		ESP-1	< 1
Guinea-pig anti-hamster gs	CF	HaLV	8– 16
		ESP-1	< 1

* Sera were tested at 4 antibody units as defined by the reaction with purified gs antigens.

† Antigens were 10–20% (v/v) cell homogenates prepared from virus-releasing cell cultures. In all cases uninfected cell controls prepared in an identical manner failed to react with these sera.

‡ Expressed as the reciprocal of the highest antigen dilution showing 3+ or greater fixation of C′ (CF), or 50% or greater inhibition in the RIPI test.

trated ESP-1 cell homogenates had antigen titres eight to ten times smaller than routinely obtained with the homologous murine systems (murine leukaemia virus grown in rodent cells). The regularity with which positive reactions were obtained at different cell passage levels, with different sources of anti-murine gs sera and in different laboratories, strongly suggested cross-reactivity in ESP-1 cells with MuLV gs antigens. Equally important in indicating specificity for MuLV was the absence of reactivity in CF tests with ESP-1 cell extracts and antisera which detect feline and hamster gs antigens.

Further evidence that the ESP-1 antigen was cross-reactive with MuLV gs antigen was obtained by RIP inhibition (RIPI) tests. The double antibody precipitation method was used[10] with free and antibody-bound antigen being separated by centrifugation through sucrose gradients. This method permits a clear separation of free antigen (molecular weight ~25,000) which remains in the upper 10% of the gradient and antibody-bound antigen which is sedimented. MuLV gs antigen was labelled with I^{125} (5×10^5 c.p.m./µg protein) by the chloramine-T method[11] and only used after a final purification through SDS-polyacrylamide gels[9]. The precipitation tests were made in conditions in which a specific anti-MuLV gs rabbit serum was diluted to give 50% precipitation (serum dilution 1 : 5,000) of approximately 0.01 µg of labelled antigen. Only homogenates of cells infected with known strains of MuLV and the ESP-1 cell showed any measurable inhibition, while cells infected with hamster or feline C-type viruses and uninfected human, hamster and mouse cells gave negative results. ESP-1 antigen titres by RIPI were consistently twenty times smaller than comparably prepared MuLV antigens from murine cell cultures.

To establish fully the relationship of the immunological determinants of the antigen in ESP-1 cells with murine C-type virus gs antigen determinants, it was necessary to show precipitin lines of identity in immunodiffusion tests, using sera specific for the murine gs antigen. Because of the relatively low antigen concentration, 50–100% (v/v) ESP-1 cell concentrates or highly concentrated supernatant fluids were used. Figs. 1*A* and *B* show two examples of precipitin lines of identity between highly purified murine gs antigen and ESP-1 concentrates using different sets of reagents prepared and tested in different laboratories. Both rabbit and guinea-pig anti-MuLV gs sera have given lines of identity using several ESP-1 preparations and purified MuLV gs antigen. Although the identity reactions were most clearly seen when ESP-1 preparations were placed between positive MuLV antigens, definite identity reactions were also seen if a positive control was placed in only one adjacent well. The specificity of the reaction shown in Fig. 1*B* was indicated by the lack of curvature of the precipitin lines when control antigens were placed in well 6. The diagnostic antisera did not react with FeLV, RaLV, or HaLV antigens, nor did they react with uninfected human cells grown in the same media. In parallel tests using antibody specific for FeLV, RaLV and HaLV gs antigens, no reactions were obtained with any of the ESP-1 preparations. These data show that the ESP-1 cells possess an antigen with determinants identical to those detected on the group-specific antigen of the murine C-type viruses.

Mouse C-type leukaemia–sarcoma viruses have previously been shown to grow in human cells[12–15]. Further, mouse and cat C-type viruses which have been grown in human cells for long periods in culture retain their original species-specific gs antigen reactivity[16]. These facts, together with the data presented above, suggest that the C-type virus particle in ESP-1 cells is a murine virus. Immunological identity of mouse and human C-type virus gs antigens, although remote, remains an alternative explanation of the present data.

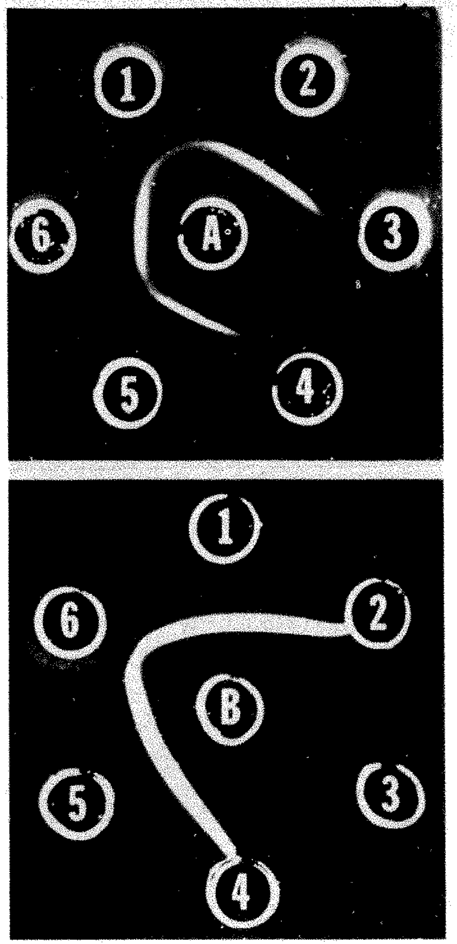

Fig. 1 Immunological identity of antigenic determinants in ESP-1 cells with MuLV gs antigen. Wells contained: Laboratory A, 1, human ESP-1 cells, 50% v/v; 2, MuLV-infected mouse cells (Kirsten strain); 3, human diploid fibroblast cells, 50% v/v; 4, FeLV (concentrated, ether disrupted); 5, MuLV-infected mouse cells (Rauscher strain); 6, purified MuLV gs; A, Rabbit 1 anti-MuLV gs. Laboratory B, 1, purified MuLV gs; 2, HaLV-infected hamster cells; 3, FeLV-infected cat cells; 4, RaLV-infected rat cells; 5, MuLV-infected rat cells; 6, ESP-1 concentrated supernatant fluid; B, rabbit 2 anti-MuLV gs.

Virus-like Agents from Patients with Hodgkin's Disease

MAGDALENA EISINGER, SYLVIA M. FOX,
ETIENNE DE HARVEN, JUNE L. BIEDLER &
F. KINGSLEY SANDERS

Sloan-Kettering Institute for Cancer Research, 410 East 68th Street, New York, New York 10021

Cultured cells from patients with Hodgkin's disease underwent changes which seemed to be accompanied by the emergence of an agent of the herpes group.

THE aetiology of Hodgkin's disease is unknown. But the age incidence of the condition[1], the fact that an individual who has a close relative with this disease is three times more likely to contract it[2], and recent evidence of possible case-to-case transmission[3], all suggest that infective agents may be involved, and that these may be viruses, although other kinds of agents have been considered in the past[4].

Two difficulties have beset all attempts to implicate particular viruses as a cause of human tumours. Most such attempts involve tissue culture studies which must begin with biopsy specimens containing more than one cell type; thus, when cell lines have been successfully established in culture, it is uncertain whether these are indeed the malignant cells. Second, tumour cells seem to be especially favourable for the multiplication of viruses, and frequently harbour passengers which are not involved in the induction of malignancy. Hodgkin's disease presents an additional difficulty. Long recognized as a mixed neoplastic and inflammatory condition, the actual malignant cells have not been positively identified even in pathological specimens, although the classical Reed–Sternberg cells may be one such[6]. In this article we report that: (*a*) we have established from patients with Hodgkin's disease a number of long term cell cultures which we suspect may contain the malignant elements; (*b*) these cells, in culture, seem to release an RNA-containing agent into the supernatant medium; (*c*) certain of these cell cultures regularly undergo "transformation" in culture, with the appearance of a large number of rounded, free floating cells, certain populations of which become capable of independent growth in suspension; (*d*) such free floating cells release into the culture medium, in addition to the RNA agent already mentioned, a second agent containing DNA; (*e*) the latter has been tentatively identified as a member of the herpes group, though its reactions are typical of neither herpes simplex nor Epstein–Barr virus [EBV, HLV]. The relationship of these agents to either the aetiology or the pathological development of Hodgkin's disease is by no means clear.

Establishment of Cell Cultures

Early attempts to cultivate lymph node material from Hodgkin's disease using classical coverslip or plasma-clot methods[7] gave cultures of predominantly mixed cell type, which died out by the end of the second week or earlier. Subsequently, a long term, free floating cell line, consisting of several types of cell, was obtained by Ito *et al.*[8], and a similar one by Pontén[9]. In the latter case the free floating cells had arisen by "lymphoblastic transformation"[10] of an apparently random growing layer of fibroblast-like cells; the free floating cells could not be cultivated in the absence of a feeder layer.

The culture method we have used depends on the fact that biopsies of Hodgkin's disease lymph nodes contain many differentiated cells such as lymphocytes and macrophages, which may be capable of at most a few divisions in culture. It was assumed that the eventual death and disruption of such cells might release products inimical to the growth of undifferentiated cells potentially capable of giving rise to cell lines. This was consistent with our failure, as of others, to initiate cultures with five trypsinized lymph node biopsy specimens, trypsinization being notoriously destructive of cells of the lymphoid series. The method finally adopted was a modified Trowell-type organ culture[11]. Fragments of lymph node 0.5–1 mm in diameter were placed directly on stainless steel grids, two to four pieces per grid in organ culture dishes[12]; the medium was Eagle's MEM + 15% foetal calf and 10% pretested human serum. The pieces remained on the grids for at least 3–4 weeks, during which time they continued to shed cells onto the surface of the dish below. As soon as the latter became covered by a confluent layer of cells (mostly round cells plus fibroblasts), the grid was transferred to a new dish, such transfers being repeated at intervals until cells were no longer deposited. The pieces of node were then transferred without trypsinization to 60 mm Petri dishes plus 5 ml. of medium; the shed cells could rarely be transferred more than a few times, and were discarded.

In all cases cells now grew out from the node fragments which were very large, pleomorphic and thinly spread, with a markedly reticular cytoplasm, many lysosomes and sometimes eosinophilic inclusions and will henceforward be termed attached cells. They were mostly mononucleated, though sometimes binucleated, with prominent nucleoli varying in number from one to four (Fig. 1). They grew individually and showed neither a fibroblastic nor an epithelial pattern of growth. When confluence was achieved, the cells in the layer were randomly oriented and could now be passaged following trypsinization. They retained their distinctive morphology for at least seven or eight passages (7–8 weeks), and cultures stored at −78° C at earlier passage levels gave rise to attached cells when revived.

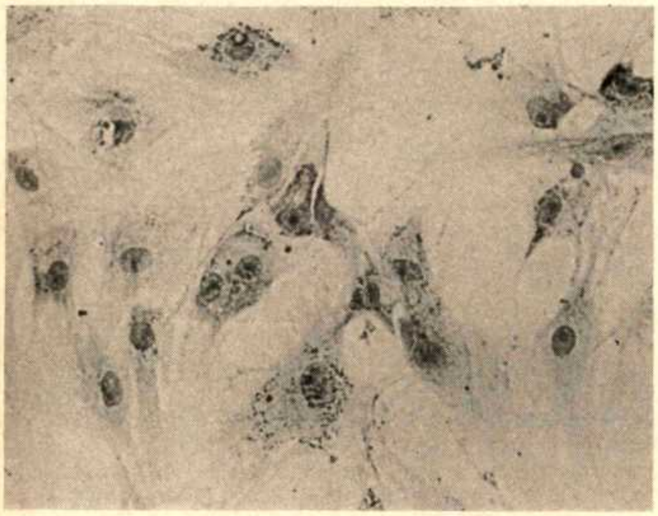

Fig. 1 Photomicrograph of cells from attached cell line (SK-HN-5b). Large, randomly arranged cells with one or two nuclei and prominent nucleoli. Reticulated cytoplasm with lysosomes (×192).

The chromosomes of the attached cell lines derived from five patients of both sexes had a model number of forty-six, the diploid number for man. In one of these five (a male) about two-thirds of the 104 metaphases counted were hypodiploid (forty-five) owing to the absence of the *Y* chromosome. Thirty-eight of fifty fully analysed karyotypes were normal, and among the twelve remaining aberrant karyotypes there were no consistent structural or numerical abnormalities. Thin sections of such cells, examined with the electron microscope, showed nuclei with dispersed euchromatin and large nucleoli. Occasional perichromatin granules were noted, very close to a thin rim of marginated heterochromatin. The cytoplasm was extremely rich in organelles of all types, an endoplasmic region being frequently distinguishable from peripheral ectoplasm. There were very many dilated rough endoplasmic reticulum cisternae containing proteinaceous material of moderate electron density, and several foci of Golgi structures. The ectoplasm showed many fewer organelles, occasional mitochondria and lysosomes being scattered among bundles of microfilaments. Structures that could be unequivocally identified as virus particles have not been seen so far.

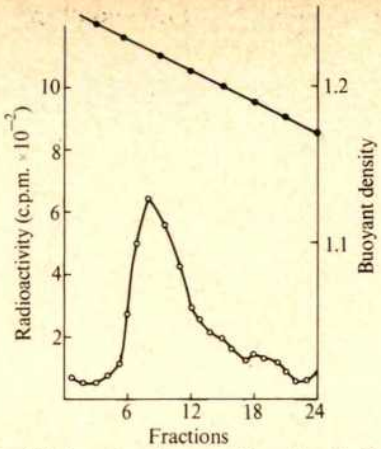

Fig. 2 Equilibrium density centrifugation in 20–58% sucrose of pelleted ^{3}H-uridine-labelled material from supernatant fluid of attached cell line SK-HN-CH.N, labelled as described in the text (16 h, 27,000 r.p.m., SW.27 rotor, 5° C). ●—●, Buoyant density; ○—○, radioactivity (c.p.m.).

Table 1 Attempts to Establish Cell Strains from Lymph Nodes, Skin, or Tumour of Patients with Hodgkin's Disease

Subject	Cultured organ	Age at biopsy (yr)	Sex	Time on grid (weeks)	Tissue in culture (weeks)	No. of cell generations	Cell strain
Hodgkin's patient 1	Lymph node	14	♂	7	27	34	SK-HN-1
Hodgkin's patient 2	Lymph node	8	♀	5	36	48	SK-HN-CH.H
	Lung tumour	9	♀	6	34	92	SK-HT-CH.H
	Skin	9	♀	2	19	70	SK-HS-CH.H
Hodgkin's patient 3	Lymph node	22	♀	3	17	40	SK-HN-3
	Spleen	22	♀	5	30	30	SK-HSp-3
Hodgkin's patient 4	Lymph	23	♂	4	17	28	SK-HN-4
Hodgkin's patient 5	Lymph	52	♂	6	10	18	SK-HN-5a
				16	7	12	SK-HN-5b
					24	180	SK-HNF-5a
					20	150	SK-HNF-5b
	Skin	52	♂	6	16	30	SK-HS-5
Hodgkin's patient 6	Lymph	15	♂	6	16	26	SK-HN-6
Hodgkin's patient 7	Lymph	23	♂	5	17	32	SK-HN-7
Hodgkin's patient 8	Lymph	14	♂	7	17	14	SK-HN-8

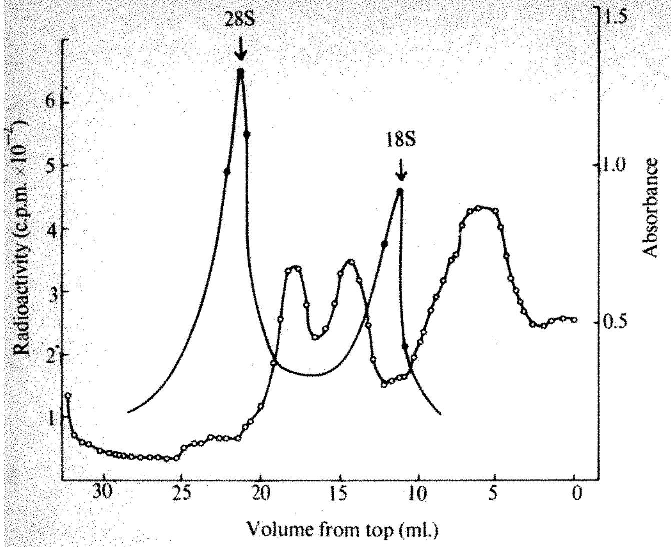

Fig. 3 Velocity sedimentation in sucrose (15–30%) of ^{3}H-RNA from the isopycnic labelled band at 1.20–1.22 liberated with SDS after dialysis to remove sucrose. 18S and 28S RNA markers from whole rat liver ribosomes (14 h, 25,000 r.p.m., SW.27 rotor, 10° C). ●—●, Abundance at 260 nm; ○—○, radioactivity (c.p.m.).

Using the above technique, it was possible to derive attached cell cultures of the same type from ten patients. In the case of eight of them (Table 1) they have now been carried for up to forty-eight cell generations. The other two were stored frozen at an early passage level; the cells, however, had a similar morphology, and none had reached "crisis"[13] before storage. In contrast, cells cultured from two normal lymph nodes went into "crisis" and failed to become established (Table 2). In two Hodgkin's cases (patients 2 and 5, Table 1) skin biopsies also gave rise to cell strains (SK–HS–CH.H, SK–HS–5), whose cells were not typical skin fibroblasts but resembled the attached cells obtained from the lymph nodes of the same individuals. One of these patients had clinical evidence of skin infiltration by tumour cells (patient 5). That the attached cells cultured by our technique may indeed be malignant was also suggested by preliminary heterotransplantation experiments in which 10^6 cells of the culture line obtained from patient 6 (SK–HN–6, Table 1) were inoculated into the cheek pouches of cortisonized weanling Syrian hamsters. Six out of twelve such inoculations gave rise to small tumours which began to regress after 1–2 weeks; 10^6 cells inoculated into the dorsal region of each of six newborn Syrian hamsters did not give rise to tumours. Cells from the skin of a normal individual gave typical fibroblast cultures which went through crisis and died out. An exception was the skin from the mother of patient 2 (Table 2), which did give rise to a continuously propagable line of fibroblasts. Patient 2, however, was homozygous for the Chediak-Higashi syndrome[14], and her mother by definition a heterozygote; it is not known what influence this rare genetic anomaly may have on the ability of fibroblasts to propagate indefinitely in culture.

Table 2 Attempts to Establish Cell Strains from Lymph Nodes and Skin of Individuals without Hodgkin's Disease

Subject	Cultured organ	Sex	Time on grid (weeks)	Tissue in culture (weeks)	No. of cell generations
Control patient 1	Lymph	♂	4	8*	14
Control patient 2	Lymph	♀	5	12*	12
Control mother of Hodgkin's patient 2	Skin	♀	2	20	70
Control patient 3 (normal)	Skin	♀	2	20*	28

* Cell strain went through "crisis" at this time and expired.

Release of Agent containing RNA

To establish whether the attached cell lines could be releasing anything resembling a virus, a search was made in the tissue culture media for material excreted by the cells which might have biophysical properties like those of viruses[15]. 5-^{3}H-uridine was incorporated in the medium at a concentration of 1 µCi/ml. Cells were labelled in log phase, 24 h after splitting semiconfluent cultures, and allowed to grow in labelled medium for 4 days. The medium was then removed (minimum volume per experiment = 300 ml.), clarified by centrifugation at 6,000 r.p.m. for 30 min at 5° C. It was then filtered through a 22 nm 'Millipore' membrane filter and pelleted at 15,000 r.p.m. for 2 h at 5° C in an SW.27 rotor. The supernatant was discarded and the pellet resuspended in three drops of Tris-EDTA buffer (0.01 M Tris, 0.001 M Tris, 0.0001 M EDTA, 0.1 M NaCl, *p*H 7.2), and layered over a 15–58% w/w sucrose gradient. The gradient was then centrifuged to equilibrium, and the gradient fractions collected and assayed for radioactivity. A typical result is shown in Fig. 2. A marked peak of radioactivity banded at a sucrose concentration corresponding to a density of 1.20–1.22. Two of our attached cell lines have been studied in this manner, and have consistently given the same result (six experiments).

Five other human and one hamster cell line were similarly labelled and treated to serve as controls. Cells from (1) a neuroblastoma (SK–N–SH), (2) a breast carcinoma (SKBR–3), (3) a continuous "floating" cell line (SK–LN) from a normal lymph node, (4) strain WI-38 embryonic lung fibroblasts, (5) the FL continuous line of amnion cells, all failed to show any uridine-labelled peak when similarly treated. (6) B34 hamster cells, a suspended cell culture line that continuously releases hamster sarcoma virus[16], served as a positive control; when labelled in the same way it gave a peak sedimenting at a density of 1.14–1.15. After labelling the attached cell lines in a similar manner with ^{3}H-thymidine, no peak was found.

It was then necessary to establish that the ^{3}H label in the 1.20–1.22 sucrose density peak was in fact in RNA, and that, if so, the RNA was not of cellular (for example, ribosomal) origin. Fig. 3 shows the result of a sedimenting ^{3}H-labelled RNA extracted from the 1.20–1.22 band on a sucrose velocity gradient at the same time as ribosomal markers. None of the three bands of labelled macromolecular RNA coincided with the 28S and 18S bands of the marker. The RNA is thus clearly not derived from ribosomes. It is, however, undoubtedly RNA, since treatment of the material with RNAase eliminated the peaks, all radioactivity now sedimenting at the top of the gradient.

There remained a trivial explanation that the ^{3}H-uridine peak was due to mycoplasma contamination; this, however, was ruled out by means of experiments to be described later.

The breadth of the labelled RNA peak (Fig. 2), however, indicates that the isopycnic band is still markedly heterogeneous. This is confirmed by electron microscopy of the material in the band. A range of particulate material is present, among which it has not yet been possible to identify any virions of characteristic morphology.

"Blastoid Transformation"

Cultures from the lymph nodes of two of the patients listed in Table 1 (patients 5 and 2) eventually underwent a further change. On continued passage the growth rate declined to a low level, and the cultures eventually became static for 2–3 weeks, though without showing a cytopathic effect. At this stage local foci of piled up cells appeared, consisting of highly basophilic "blastoid" round cells. At their first appearance the latter seemed to be "nested" within the cytoplasm of an attached cell, for they had a clear halo around them, which could be enhanced by the use of phase-contrast illumination (Fig. 4*a*). This did not seem to be the result of phagocytosis, because debris or degenerating cells were not found in this situation; moreover, many of the rounded cells could be seen to be in mitosis, while still within the cytoplasm of the reticular cells (Fig. 4*b*). At an intermediate stage of "transformation", practically every reticular cell could be seen to have one or more round cells within it. The question remains open as to whether the round cells actually arise within the reticular cells, or enter the latter's cytoplasm to complete their development.

This process of "blastoid transformation" continued for 4–5 weeks, when the cultures from one patient (Table 1, No. 5) had become entirely composed of free floating cells (blastoid cells) (Fig. 5) with large variations in cell size and number of nuclei; at the same time the growth rate increased approximately eight-fold, considerably exceeding that of the parent culture. Transformation occurred on two different occasions with separate samples from this same patient, each at about the same time in the history of the resultant cell line. On the first occasion transformation occurred after lymph node fragments had remained for 1 month on the grid, followed by nine transfers as monolayer cultures. The second time the fragments were on the grid for 4 months, followed by six monolayer passages. A single stock of reticular cells from one of these cell lines before transformation was kept stored at −78° C; on four later occasions, when cells from this stock were thawed out and subsequently propagated, complete transformation into blastoid cells took place. Cells from a second patient (2) also gave rise to blastoid cells of the type described, but in this case they could only be propagated by using a feeder layer, and thus resembled those of Pontén[9]. At the time of writing, attached cell lines from three more patients (6, 7 and 8) are beginning to undergo similar changes.

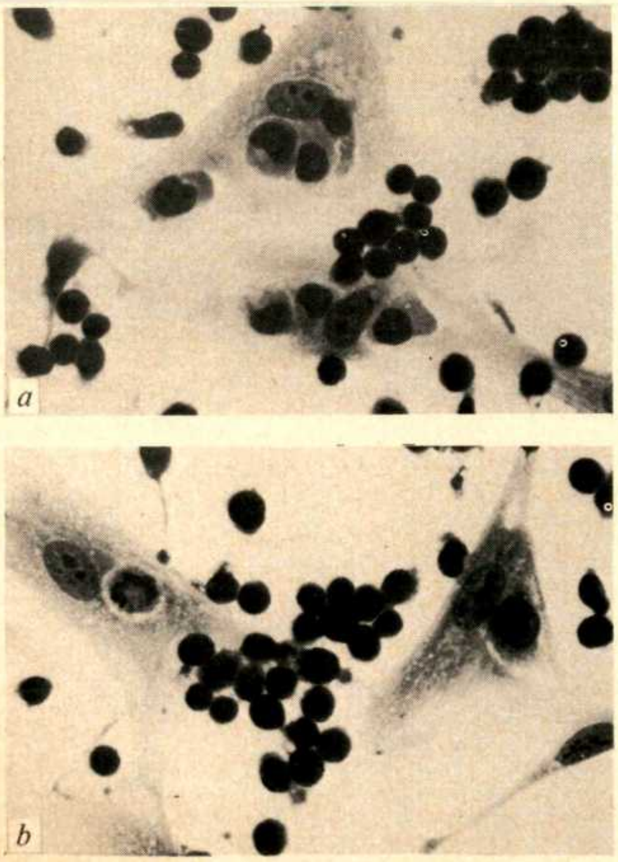

Fig. 4 *a*, "Blastoid transformation" intermediate stage (×384). Note cells nested within the cytoplasm of settled cells; multinucleate giant cell. *b*, Further advanced "blastoid transformation" (×384). Note group of cells in mitosis.

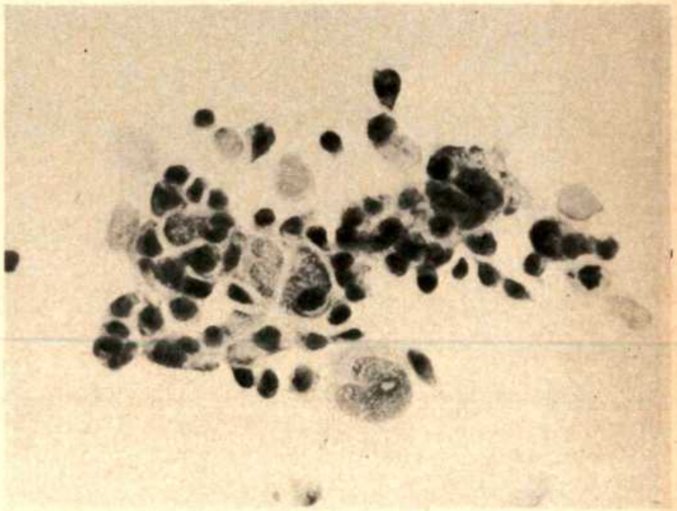

Fig. 5 Cells from suspended culture of transformed cells. Note large variations in cell size and nuclei (×375).

At least three types of blastoid cells could be distinguished (Fig. 5): (*a*) small, highly basophilic cells with a large round nucleus; (*b*) medium sized, less basophilic, sometimes vacuolated cells, with a large nucleus containing multiple irregularly shaped nucleoli; (*c*) multinucleated giant cells with many nucleoli. The floating cells generally also had forty-six chromosomes although two out of forty-one cells from the floating cell line derived from patient 5 also lacked the *Y* chromosome; a notable feature of these cells was the elevated frequency of enhanced secondary constrictions of chromosomes 1, 9 and 16.

The blastoid cells differed strikingly in ultrastructure from the attached cells. Their nuclei showed more condensed heterochromatin and larger numbers of perichromatin granules, and throughout their cytoplasm mitochondria with a dense matrix and conspicuous "mitochondrial ribosomes" could be seen. No boundary was apparent between ectoplasm and endoplasm, and the microfilaments, so conspicuous in the reticular cell lines, were barely visible. Moreover, the endoplasmic reticulum was poorly developed, and its cisternae contained no accumulated secretion product. Most ribosomes appeared as "free" monosomes, while in the reticular cells most of them were attached to membranes in typical "polysome" patterns. Clumps of blastoid cells showed many examples of close contact of their plasmalemma, giving the appearance of tight junctions. Thus while the reticular cells have some of the ultrastructural features of histiocytes, the floating blastoid cells resemble blastoid elements of the haemopoietic system.

Release of Agent containing DNA

Labelling experiments were also performed with one of the suspended cell lines that arose following the "blastoid" transformation just described (patient 5). The technique was the same as that used with the settled cell lines. 5-^{3}H-uridine still became incorporated into material banding isopycnically on sucrose at 1.20–1.22 (Fig. 6). But when ^{3}H-thymidine instead of 5-^{3}H-uridine was used, a strongly labelled DNA-containing peak was consistently found banding at the same position in the gradient (1.20–1.22; Fig. 7). At the outset, it was suspected that both the DNA and RNA-containing bands might be due to concurrent mycoplasma contamination, and bacteriological examination revealed that this culture line was indeed infected with mycoplasma. The following evidence, however, makes it unlikely that mycoplasma was responsible for this band.

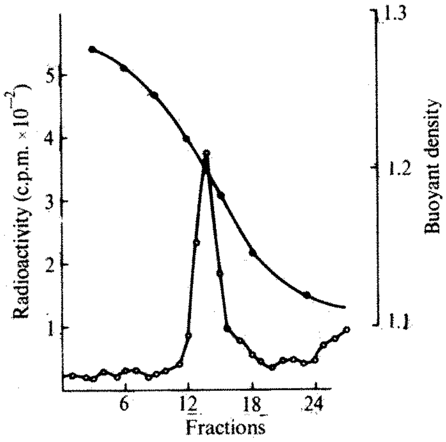

Fig. 6 Equilibrium density centrifugation in 20–58% w/w sucrose of pelleted ^{3}H-uridine-labelled material from supernatant fluid of "transformed" suspended cell culture SK-HNF-5b (16 h, 27,000 r.p.m., SW.27, 5° C). Symbols as in Fig. 2.

(*a*) Mycoplasma, isolated from the culture line itself, grown up in broth and concentrated by centrifugation, banded on sucrose at an equivalent density of 1.24–1.26, many fractions further down the gradient than the labelled band mentioned above. (*b*) Cultures of FL amnion cells and WI-38 fibroblasts were deliberately infected with a high level of this same mycoplasma, and then labelled with ^{3}H-uridine in the manner described. The tissue culture fluids were then processed in the same way as before, and the concentrates banded isopycnically in sucrose. No labelled peak was seen. (*c*) The mycoplasma-contaminated "blastoid" cell line was treated by Dr J. Fogh until there was no longer any evidence of mycoplasma. ^{3}H-thymidine labelling was undertaken, this time in another laboratory known to be free from mycoplasma, and the fluids examined. A ^{3}H-labelled peak at 1.20–1.22 was again present, of greater size than before. (*d*) Electron microscope examination of thin sections of the pelleted supernatant revealed the presence of double-enveloped nucleocapsids typical of the herpesvirus group. (*e*) There was also immunological evidence—to be discussed in the next section—of the presence of herpesvirus antigens, both in the cells and in the material from the sucrose band.

Serology of DNA containing Agent

Serological studies of the SK-HNF-5 cell line are being conducted in collaboration with Miss Gayla Geering and Drs Germaine Trempe, T. Takahashi and Lloyd Old. As expected from the morphological evidence of the presence of an associated herpesvirus, herpesvirus gs antigen has been demonstrated in the pelleted virus. Immunodiffusion and immunofluorescence studies have failed to show EB virus-related antigen in the SK-HNF-5 cell line; however, a new antigen has been found in the cell line by immunodiffusion, and precipitating antibody to this antigen is found in the sera of a high proportion of normal human subjects.

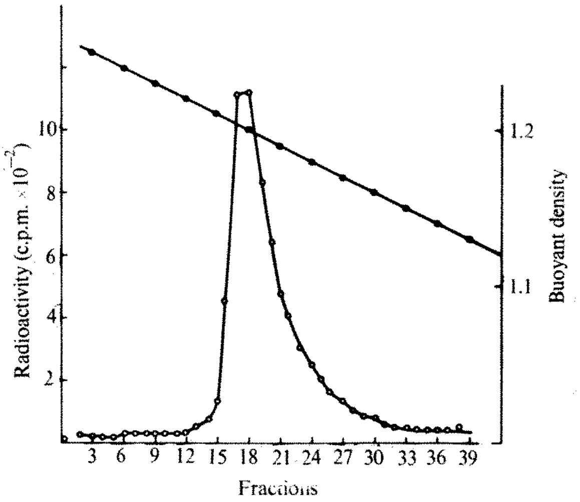

Fig. 7 Equilibrium density centrifugation in 20–58% w/w sucrose of pelleted ^{3}H-thymidine-labelled material from supernatant fluid of "transformed" suspended cell culture SK-HNF-5b (16 h, 27,000 r.p.m., SW.27 rotor, 5° C). Symbols as in Fig. 2.

Our findings suggest that the process of "blastoid transformation" in this case may have been accompanied by the emergence of an agent of the herpes group. Further experiments are in progress to discover whether a similar phenomenon occurred during the other instances of transformation reported.

This work was supported in part by a grant from the National Cancer Institute. In addition to those mentioned we thank Dr Charles W. Young for clinical material; Dr Jørgen Fogh for mycoplasma studies: Dr Mathilde Krum for help with chromosome studies and histology; Miss Barbara Dziuban, Mr Edward Bittar and Miss Barbara A. Spengler for technical assistance; and Mrs Emma M. Tessier and Miss Patricia Potenza for secretarial assistance.

Eclipsing Binary Model of Cygnus XR-1

AGRAWAL *et al.*[1] present an interesting observation of the variable X-ray source Cygnus XR-1 at energies above 20 keV. This communication points out that their observations may be consistently interpreted in terms of the eclipsing binary model for the source that was originally outlined in an article by myself[2] (article 1).

Agrawal *et al.* observed the source in nineteen consecutive periods of approximately 5 min from 0002 to 0315 UT, on April 6, 1971. The mean count rate in the 22.5–99 keV energy range for periods 1 to 12 was 260 counts per min (although non-random variations in the count rate appear to be present) and there was "no significant variation" in this source count rate for the following four periods (13 to 16). The three succeeding periods, however (17 to 19), show "considerably lower values" of source count rate; the authors infer from these results the fact that the source "decreased from the mean value corresponding to (periods) 1–12 by a factor of ~2. The observations (between periods 16 and 17) are consecutive in time and therefore the fall in intensity has taken place within a few minutes".

According to the eclipsing binary model outlined in article 1, Cygnus XR-1 is composed of a source of small angular extent (either a dense star or a small, optically thin region associated with it) having a spectrum similar to that of a black body at $kT=12.5$ keV and a non-X-radiating companion which eclipses it at intervals of 2.9850 d. The system is surrounded by an X-radiating plasma the photon flux of which between 1 and 100 keV can be approximated by a power law spectrum the exponent of which is -1.7. Using an epoch of (primary) minimum derived in article 1 of JD 2 439 382.71 [which is uncertain to something like 1 h], a minimum would thus be predicted to occur at JD 2 441 047.88. Because the eclipse minimum was shown in article 1 to last at least 0.66 day but less than 0.80 day, this would predict an occultation of the black body source sometime between 2330 and 0115 UT on April 5–6, 1971. If we accept the discrepancy of 1 h as being caused by the uncertainty in the epoch of primary minimum, it is possible to interpret the observations of Agrawal *et al.* as being caused by the immersion of the black body source behind its non X-radiating companion. To support this interpretation we note first that the variation occurs in the right direction, that is, a decrease in flux before the time of minimum, second that the flux decrease in the 22–99 keV range is of the amount (~1/2 the maximum flux observed from Cygnus XR-1) ascribed to the black body source in the eclipsing model, that is, it is the amount which, added to the state of minimum flux defined in article 1, would produce the state of maximum flux. Third, no effect was seen over the same time period in the energy region 99–154 keV by Agrawal *et al.*[1]. Using the data in their Table 1, the 19 observations had a χ^2 of 19.5; 39.2% of all random distributions are more random than this for 18 degrees of freedom. Thus, the observation in this energy region is consistent with that expected from the random arrival of photons from a non-varying source, which in the eclipsing binary model would be identified with the X-radiating plasma surrounding the system. The black body source intensity above 100 keV, of course, is negligible with $kT=12.5$ keV. Fourth, the total immersion of the black body takes place over a short time period, that is, over a period of minutes. This is the expected time of occultation of an object of a few kilometres diameter at a distance of ~1 kpc in an orbit of period 3 days about a solar size object. If the flux difference between the states of maximum and minimum flux is taken to be $\sim 1.5\times10^{-8}$ ergs cm^{-2} s, then the distance of the 1.5×10^{8} K black body producing this flux is 0.9 R kpc, where R is the radius of the black body in kilometres. The irregularity in the flux immediately before immersion is perhaps related to the line of sight passing through a region near a distorted stellar atmosphere the boundary of which is not sharp in the sense of the solar limb.

Since the publication of article 1, three other observations of Cyg XR-1 have been made in the region above 20 keV. Weber and Reinert (private communication) observed the source on JD 2 440 352.87 and obtained a spectrum consistent with a state of minimum flux. The nearest minimum predicted in article 1 was at JD 2 440 352.83, consistent with the observation. Haymes and Harnden[3] observed the source between JD 2 440 377.78 and 378.07; their resultant, high quality spectrum is nearly coincident with their previous measurement of the object in the state of maximum flux. The nearest minimum predicted in article 1 occurs at JD 2 440 376.71, 1.22 days before, and so is consistent with the observed state. Agrawal *et al.*[4] also observed Cyg XR-1 between JD 2 440 328.36 and 328.47; the spectrum they derived would be classified as "uncertain" (with regard to the level of flux) according to the criteria outlined in article 1. Because the nearest minimum is predicted to occur at JD 2 440 328.96, this observation must have occurred at a time of maximum intensity.

Observation of Cyg XR-1 from the satellite Explorer 42 (ref. 5) in the 2.4 to 6.9 keV region indicated that approximately 25% of the flux exhibits short time variability. Although no eclipse phenomena seem to be present in this energy region (see article 1), this observation clearly indicates the multiple source nature of the object. The observation of the variable source Cen X-3 from the same satellite[6] seems to indicate the same type of pulsation observed from Cyg XR-1 in this energy range. Since Cen X-3 is best fitted by a black body spectrum of 3.3×10^{7} K, it is tempting to interpret the smooth variation in flux level in Fig. 1 of ref. 6 as the immersion of an eclipsing binary system. The lower temperature of the black body and the less intense continuous radiation relative to it make the variability more evident for this source in the satellite's lower energy range of observation.

The eclipsing binary model for the variability of Cyg XR-1 as presented in article 1 thus still seems to be consistent with all observations of the object so far.

Optical Identification of Cygnus X-1

THE star HD 226868 is coincident, within a 3″ error, with a faint and possibly variable radio source which itself is coincident, though with a large uncertainty, with the Cygnus X-1 pulsating X-ray star[1].

Table 1 Data on HD 226868 (= BD 34° 3815)

$V=8.89$; $(B-V)=+0.85$; $(U-B)=-0.24$ (Hiltner[3])		
S_p	$=$BOIb	(Morgan, Code and Whitford[2]; RGO)
$V_r(*)$	$=-12$ km s^{-1}	(Seyfert and Popper[8])
$V_r(K)$	$=-24$ km s^{-1}	
	$=-13\pm7$ km s^{-1}	(RGO)
Equivalent width of K line		
	$=0.3$ Å	(Seyfert and Popper[8])
	$=0.6\pm0.1$ Å	(RGO)
Central depth of diffuse interstellar line (4430 Å)		
	$=9\pm2\%$	(RGO)
Q	$=-0.89$ mags	
$E_{(B-V)}$	$=1.07$ mags	
m_0-M	$=11.5$ mags	
d	$=2.0\pm0.5$ kpc	

Table 1 lists information about HD 226868 obtained from the literature and from spectrograms taken by observers at the Royal Greenwich Observatory (RGO) with the image tube and photographic spectrographs attached to the 98 inch telescope; the measurements were made between July 26 and August 4, 1971. The RGO spectra were at dispersions of 60, 70 and 180 Å mm^{-1} over the spectral range 3600 to 5200 Å. The star appears to be a normal BOIb supergiant as classified by Morgan *et al.*[2]. (The visibility of the high Balmer lines in HD 226868 is slightly less than the visibility of those in a comparison star HD 192422, BO.5Ib, which tends to decrease its luminosity towards II.)

The allocation of the spectral type BOIb is supported by the photoelectric colours of Hiltner[3] which give

$$Q=(U-B)-0.72(B-V)-0.05(B-V)E_{B-V}= -0.89$$

agreeing precisely with the standard value[4].

The spectroscopic distance modulus of HD 226868, calculated using $M_v= -5.8$ (ref. 5) and the value, $R=3.0$, for the ratio of total to selective absorption in this region[6], is 11.5 mags, corresponding to a distance of 2.0 kpc. The chief uncertainty in the distance modulus arises from cosmic dispersion in the absolute magnitude of the spectral type, and corresponds to an error in the distance of ±0.5 kpc. The intensities of the interstellar K-line and 4430 Å diffuse band are consistent with the amount of reddening and the distance to the star. The kinematic distances of the star and K-line absorption are liable to large uncertainty because the star is near the null points of the galactic velocity field, but they are also consistent with the spectroscopic distance modulus.

The distance of 2.0 kpc which we ascribe to the star is, apparently, inconsistent with the upper limit of 1.0 kpc placed on the distance of Cygnus X-1 by Gursky *et al.*[7] from the low energy turn-off in its X-ray spectrum due to photoelectric absorption in the interstellar medium. But because of the tentative identification of the supergiant with Cyg X-1 and the uncertainties expressed by Gursky *et al.* about the accuracy of their method, we feel it premature to attempt to save the phenomenon. If the double coincidence of position between the Cyg X-1 source, the radio star and the supergiant is too strong to be by chance, the X-ray source may be a companion to the supergiant, rather than identical to it. If the X-ray source has an optical absolute magnitude of +4, like the Crab Nebula pulsar, its optical luminosity is 10^{-4} times that of the supergiant. A distance of 2.0 kpc would imply that the observed power output in the X-ray region (0.5 to 100 keV) would be more than 10^{37} erg s^{-1} and comparable with the Crab Nebula.

Possible Black Hole in Beta Lyrae

β LYRAE is one of the most controversial and puzzling of binary systems[1]. The central issue concerns the absolute masses of the two components. The one-spectrum radial-velocity curve does not reveal what those masses are, but any pair of masses satisfying its mass function make the system remarkable. Table 1 gives pairs of masses which satisfy the observed 8.5 $M_{\odot}$ mass function[2]. Here $q=M_{\rm BRT}/M_{\rm FNT}$, and the entries in the table are the minimum masses allowable—that is, the orbital inclination angle is assumed to be 90°. Early investigators, faced with the absence of the secondary component in the spectrograms at all phases, assumed that the components of the system obey a mass-luminosity law and favoured a mass ratio considerably larger than unity. This, however, results in very large masses, especially for the B8 primary. Three arguments have since been put forward which make the choice $q>1$ dubious. First, Sahade[3] has called attention to the behaviour of the unusual emission features present in the spectrograms, noting that, should they be associated with the secondary star, a value for the mass ratio considerably less than unity results. Second, a similar small value comes from a distance determination by Abt[4], which was based on β Lyrae's co-motion with few stars. As these were found to be ordinary main sequence objects, the absolute magnitude of β Lyrae was determined to be $M_v = -3.4$, which agrees with the spectroscopic luminosity class. So modest a luminosity can hardly be associated with such a massive primary component as indicated for $q > 1$. Finally, Woolf[5] has used Abt's distance in combination with an assumed brightness temperature to find the absolute area of the primary star and thus its absolute "radius". Further, assuming that β Lyrae A fills its Roche lobe, this "radius" is compared to the observed value of $a_1 \sin i$ to obtain the mass ratio of the system, again giving $q < 1$.

Table 1 Minimum Absolute Masses which Satisfy the Observed Mass Function

$M_{\rm BRT}/M_{\rm FNT}$	$M_{\rm FNT}$ (solar masses)	$M_{\rm BRT(B8)}$ (solar masses)
0	8.5	0
1/4	13.3	3.3
1/2	19.2	9.6
1/1	34.0	34.0
2/1	76.5	153.0

It is difficult to accept such a small mass ratio for the system, however, because the secondary must then be extraordinarily underluminous for its mass. Nevertheless, I shall show that this is a necessary consequence of the present observational evidence.

Although spectroscopy does not reveal the mass ratio of β Lyrae's components, the photometry of the system provides vital information through the photometric effect of tidal and rotational distortion. The aim of this article is to use this effect to determine the mass ratio by the method of fitting theoretical light curves to the observations throughout the phase interval between eclipses. The principle is straightforward, yet the method has not had widespread application. One reason is that the mass ratio is only one of several parameters which influence the out-of-eclipse variation and thus it is usually weakly determined. Furthermore, it has been difficult until recently to carry out calculations on the light changes of stars which display such severe photometric distortion as β Lyrae. The calculations presented here are adapted from a program for computing monochromatic, complete light curves of close binaries in which all the distortion and mutual irradiation effects are considered. The computer program and its application are presented in detail elsewhere[6].

I shall show that β Lyrae is a most interesting exception in which the photometric technique can be applied to the determination of the mass ratio. Two factors are responsible for this. First, the primary (more luminous) component is in contact with its Roche lobe, a fact made evident by the pattern of gas-streaming in the system, pointed out by Struve[1] and also by Sahade[3]. Thus its relative size is uniquely determined by any assumed value of q. Second, this component is the only one which contributes significantly to the observed light variation between eclipses. The secondary may thus be neglected in the theoretical calculations, reducing considerably the number of free parameters, and elevating the mass ratio to the role of the dominant parameter. Because the neglect of the faint component is important to the application of the method, its justification will be considered in some detail, using information from the well known spectroscopic data and the recently published light curve of Larsson-Leander[7], which resulted from the 1959 IAU International Campaign on β Lyrae.

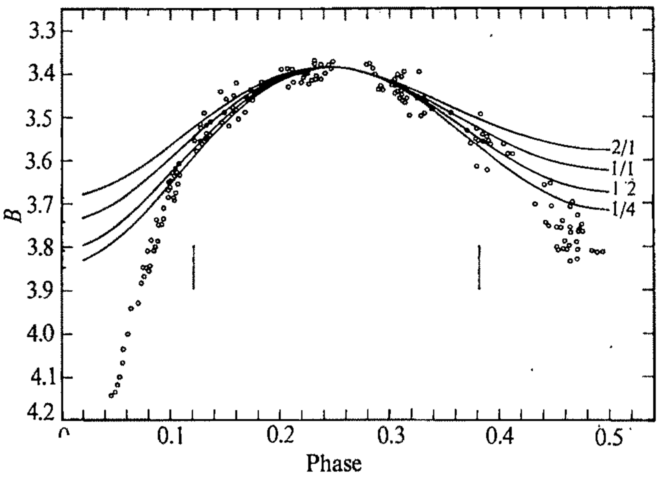

Fig. 1 The B light curve of Larsson-Leander with the theoretical curves as solid lines, given for labelled values of the mass ratio $M_{\rm BRT(B8)}/M_{\rm FNT(INV)}$. Other required parameters for the calculation are given in the text. The primary eclipse egress is shown and observations in the range of phases from 0.5 to 0.89 have been reflected about phase 0.5.

The principal feature of the spectroscopy of this system is the total absence of an ordinary absorption spectrum attributable to a secondary component, even at mid-primary eclipse. At this phase, the light level drops to 48% of its value at the quarter phases. As the absence of one member of a binary from spectrograms is commonly taken to indicate that a factor of at least six separates the luminosity of the stars, it may be concluded that the secondary is responsible for no more than 8% of the light of the system. (The $B-V$ colour curve is quite flat so that this statement is true for either yellow or blue light.) Now consider the light curve shown in Fig. 1. It is noteworthy that the phase of external tangency, marking the end of eclipse, is visible clearly at a phase of 0.11, from which it can be seen that the amplitude of the eclipse effects reaches 0.20 magnitudes. A secondary with 8%, or less, of the system's light cannot be responsible for such changes. In fact, careful consideration shows that what the observations do reveal, with considerable fidelity, is the tidal and rotational distortion of the primary component alone. This can be seen by correcting the observations for the presence of a supposed 8% secondary, allowing, for purposes which will become evident, that it is somewhere in the distortion range between a perfectly spherical and a fully distorted or contact star. Treating the spherical case first, it is merely necessary to subtract 8% light from the observations at all phases. This results, on a magnitude scale, in a slight increase in the amplitude of the out-of-eclipse light variation amounting to 0.015 magnitudes. As the secondary is allowed to be more distorted, it is found that the corrected data approach more closely the original observations.

The theoretical calculations thus give the light variation of one contact component only, as a function of phase. The computations depend on just four parameters, in addition to the mass ratio. As the mass ratio sets the size of the contact primary in this case, the inclination angle is the only other geometrical parameter required and it has been assumed to be 90°. The coefficient of limb darkening was taken as 0.60, somewhat larger than theory predicts. The gravity-darkening law was that for an atmosphere in radiative equilibrium (von Zeipel's law). An effective temperature of 11,000 K was assumed, but the calculations are not sensitive to this parameter. The choice of 90° inclination, radiative equilibrium, and a coefficient of limb darkening larger than expected, as well as the neglect of a possible light contribution by the secondary, all insure the greatest light variation possible for any given mass ratio. This means than an upper limit for the mass ratio $M_{\rm BRT}/M_{\rm FNT}$ is found here. The results of the theoretical calculations for selected values of the mass ratio are shown as solid curves in Fig. 1. It is evident that the primary has the minor share of the system's mass, and that very likely $q \simeq 1/2$ is a realistic upper limit. If the secondary happens to be spherical, and contributes the maximum amount, 8%, to the light of the system, then it is conceivable that the mass ratio is a factor of two smaller. A significantly smaller mass ratio would also be appropriate if the primary could somehow have a convective atmosphere. It is also conceivable that the system's inclination angle differs so significantly from 90° that further reduction would be needed. Thus it is seen that the primary must not have more than ~35% of the mass of the system.

For $q = 1/2$, the absolute masses resulting for the primary and secondary are approximately 10 $M_{\odot}$ and 20 $M_{\odot}$ respectively. The mass of the primary is in good agreement with that determined by Abt from the slightly evolved position of β Lyrae A on the colour-luminosity diagram, but perhaps the evolutionary state of the star is also a function of its duplicity and the star may not be in equilibrium. It is now virtually certain that the secondary must be a most remarkable object, at least four magnitudes underluminous for its mass. Such a large value for its mass excludes the possibility of its being a white dwarf or neutron star, but it may be a black hole, or perhaps some previously unknown stellar state.

The photometric data furnish no information that the secondary is a collapsed object. In fact, there is clear indication of a geometrical eclipse in which about 1/3 of the primary is hidden, so the eclipsing body must be substantial in size, yet it must be within its Roche critical surface, if the primary is at its own lobe. This is because the principal eclipse is over at a phase of 0.11, whereas the eclipse of two contact components would continue until a phase of 0.16 regardless of the mass ratio[8]. It is quite likely that the agent responsible for the primary eclipse is a disk, the existence of which is given strong credibility by the polarimetric work of Rucinski[9]. There also certainly appears to be a light loss due to eclipse at the secondary minimum. This loss does not seem to be due to the eclipse of the light of the primary reflected from the disk because then the reflexion effect of the system would have to be quite pronounced, which is not at all the case, so it is conceivable that the secondary itself is actually eclipsed. It would probably be meaningless to use the eclipse light loss at the two minima to infer the surface brightness ratio of the two components, because there exists the likely contribution of the disk to the principal minimum. Despite these difficulties in interpretation of the complete light curve of this star, the results for the mass ratio obtained here cannot be vitiated unless one is prepared to believe that the light variation between eclipses has some unknown and mysterious source. In view of the strong evidence for the primary being at its Roche lobe and also dominating the light of the system, the basis for such an idea is totally lacking.

On the contrary, the evidence is conclusive for the presence of a massive, underluminous object in the system of β Lyrae and we should probably look to it for an explanation of the remaining problems of the light curve.

An important item of evidence furnished by the identification of a black hole in a close binary system is that the collapse must have taken place without much mass loss because the system was not disrupted; 20 $M_{\odot}$ must be approximately the mass of the pre-collapse object. It can also be suggested that the disk about the secondary was created by a mass-shedding process during collapse. As the secondary is invisible because of its small size, there is no reason to consider that the disk is an opaque, star-hiding body[10], having a considerable fraction of the mass of the system[5]. The stability of such a ring would be questionable, so it is probable that only a small fraction of the mass of the collapsing object was lost to the disk.

The importance of this system for understanding the nature of massive, underluminous stars is great, and it is necessary to encourage all pertinent observations. Finally, it is ironic to note that β Lyrae, the prototype of all β Lyrae systems, is not a β Lyrae system.

Compact Radio Sources in the Galactic Nucleus

SMALL-SCALE radio structure within Sgr A, the source identified with the galactic centre, is of great interest because of the recent discovery of similar structure in the infrared[1] and because of current speculation on black holes in the galactic nucleus[2]. In this communication we describe new observations

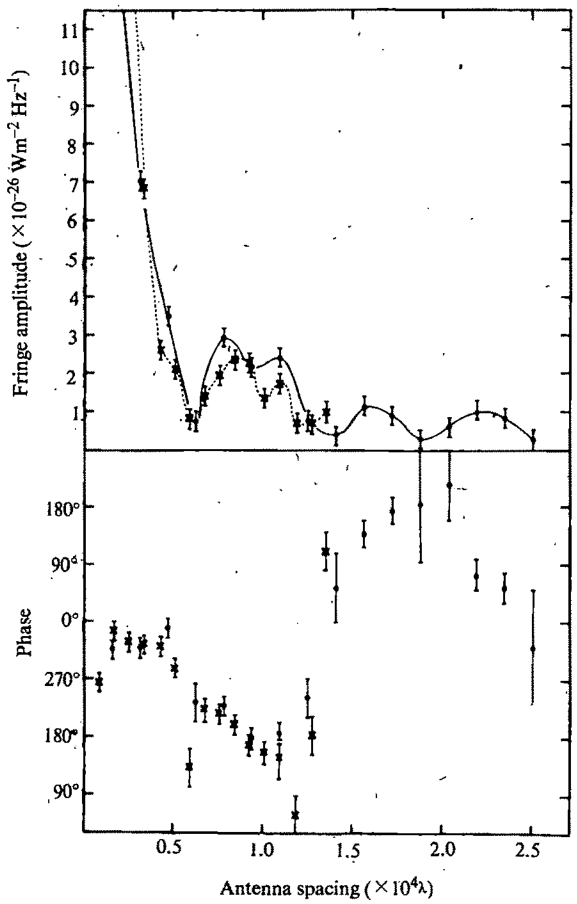

Fig. 1 Fringe amplitude and phase for Sgr A at transit at (×) 2.7 and (●) 5 GHz.

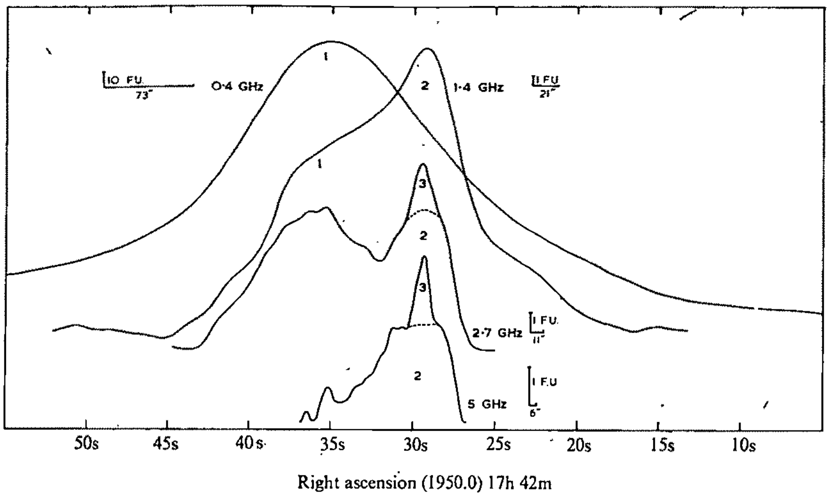

Fig. 2 Strip brightness distributions in right ascension for Sgr A at transit at 0.4, 1.4, 2.7 and 5 GHz. Horizontal bar indicates beamwidth, vertical bar indicates intensity of a point source. The components are numbered as in Table 1.

of Sgr A with the Cambridge 1 mile telescope at frequencies of 2.7 and 5 GHz. The beamwidths in right ascension were respectively 11 and 6 arcsec, the best of these being the highest resolution yet applied to the galactic centre. The observations suggest a three component model for Sgr A, and confirm the existence of radio structure on a scale of 10 arcsec. The relation of these compact radio sources to the infrared emission is also examined.

The observations were made between January and March 1971 at centre frequencies of 2.6970 and 4.9938 GHz, with sixteen antenna spacings along an east–west baseline. At each frequency the system temperature was about 1,000 K and the infrared bandwidth was 4 MHz. All observations were made during ±1 h of meridian transit, with the antennas pointing 8 arcmin north of the true declination of the source to allow for atmospheric refraction. The primary source for calibration of phase and intensity was 3C 147, which was assumed to have flux densities of 13.0 and 8.2 flux units at 2.7 and 5 GHz respectively. The data were averaged for intervals of 15 min, for an r.m.s. sensitivity of 0.3 flux units in the fringe amplitude. In our experiment, the telescope produced a principal response whose half-width in right ascension was 11 and 6 arcsec at 2.7 and 5 GHz, with first grating lobes separated from the main beam by 4.1 and 2.2 arcmin in right ascension respectively.

Previous observations of this type[3–5] have provided curves of fringe visibility and phase for Sgr A up to baselines of 2000 λ at frequencies ~1 GHz. The maximum baseline of the present observations is 25,000 λ at 5 GHz. The fringe visibility and phase from the new observations are shown in Fig. 1 for the galactic centre at transit. At spacings <4000 λ the curves show the tail of the response to the main part of Sgr A, which has an angular diameter ~3 arcmin. This is the part of the visibility function that has appeared in previous interferometric observations of the source. At spacings >4000 λ, the new visibility function shows the presence of fine structure in the source at even the longest spacing. The existence of fine structure was originally recognized by Ekers and Lynden-Bell (private communication) who used the interferometer at the Owens Valley Radio Observatory.

Before Fourier inversion of the observations, the fringe amplitudes were multiplied by a Gaussian weighting function which fell to a value of 30% at the largest spacing; this weighting function reduced sidelobes to 5% or less. The synthesized fan beam was centred on declination −28° 59′ 30″, and the beamwidth in declination was 16 and 9 arcmin at 2.7 and 5 GHz respectively.

Table 1 Model Proposed for Sgr A

Component name	r.a. 1950	dec. 1950	Halfwidth in r.a.	Flux density (× 10^{-26} W m^{-2} Hz^{-1})			
				0.4	1.4	2.7	5.0 GHz
1 Sgr A East	17 h 42 m 36 s ±1 s	−28° 59′ 00″ ±60″	150″ ±30″	250±50	160±30	>80	—
2 Sgr A West	17 h 42 m 29.3 s ±0.3 s	−28° 59′ 15″ ±50″	45″ ± 5″	—	30± 5	25±5	25±5
3 Compact structure*	17 h 42 m 29.3 s ±0.1 s	−28° 59′ 20″ ±30″	10″ ± 2″	—	—	3±1	3±1

* Only the strongest feature has been tabulated.

The resulting brightness distributions are shown in Fig. 2. The new data at 2.7 and 5 GHz are shown together with earlier scans obtained at 0.408 and 1.407 GHz with sixteen spacings of the same telescope[6]. The profiles clearly show the shift in position of the peak of the source as noted by other observers[6–9] and also show the existence of a prominent small diameter source at higher frequencies. The profile at 5 GHz, however, does not show structure of low spatial frequency (that is, of angular size >2 arcmin) that may be present, because of the limited number of antenna spacings used.

Fourier transforms were also made of the data taken at local hour angles ±00 h 45 m, which correspond to position angles ±6° across the source. A comparison of the three scans gives information on the declination of the various components and suggests a three component model of Sgr A which is summarized in Table 1. We emphasize, however, the uncertainties in this model which are a consequence of our limited coverage in the Fourier transform plane. In particular, there seem to be additional components of size <10 arcsec and intensity <1 flux unit, which we have not tabulated. Among these are the peaks at r.a. 17 h 42 m 35 s, and other peaks or ridges to the east and west of the 3 flux unit source at 17 h 42 m 29.3 s.

We interpret the radio spectra of the components in Table 1 as follows. The 2.5 arcmin source at r.a. 17 h 42 m 36 s (Sgr A East) is probably non-thermal because: (i) it emits most of the flux, and the spectral index $\alpha < -0.25$ ($S \propto \nu^{\alpha}$) derived from lunar occultations[10] refers chiefly to this component. The predominance of this source at 0.2 to 0.4 GHz explains the increase in diameter of Sgr A with decreasing frequency and also its position shift to the east; (ii) H109α recombination line emission is at least an order of magnitude less than one would expect from a thermal source of this flux density[11]; (iii) for a thermal source of this size and intensity to be optically thin at 200 MHz (ref. 10), the electron temperature would have to be $>10^5$ K.

Both sources in the complex at 17 h 42 m 29.3 s, consisting of Sgr A West and the compact structure with diameter ~10 arcsec, appear to have flat spectra. At present we cannot distinguish between a thermal and non-thermal origin for the sources in this region. If they are thermal, then their linear sizes and flux densities are comparable with those of compact H II regions[12]. The sources would become optically thick below 1 GHz and this would help to explain the position shift at low frequencies. If, on the other hand, these sources are non-thermal, they must simply have a flatter spectrum than Sgr A East. The same effects of diameter increase and position shift would then be observed in lunar occultations. On a synchrotron interpretation, the compact component would be similar to the bright radio knots seen in Cas A (ref. 13) and would have a minimum energy of 10^{46} erg.

On the basis of existing measurements, the group of infrared sources prominent at 5 to 20 μm (ref. 1) is displaced by about 10 to 15 arcsec to the east of our component 3. None of the localized sources at these infrared wavelengths coincides with any of the radio components. This may be similar to the situation in some H II regions, for example, the Orion Nebula, where the IR nebula[14] seen at 10 to 20 μm does not coincide with the radio peak.

As the small components seen in Sgr A at both radio and infrared wavelengths have diameters of the order of a light year or less, it may be possible to detect intensity variations on a timescale of a few months. We also suggest that the source be monitored for interplanetary scintillation, which might reveal even smaller radio components in Sgr A.

We thank Drs R. D. Ekers, D. Lynden-Bell, F. J. Low and G. H. Rieke for informing us of their results before publication and G. H. Macdonald for permission to refer to unpublished work. D. D. was supported by a Frank Knox fellowship and A. H. M. M. by an SRC studentship.

Reduction of Dinitrogen in Aqueous Solution

NITROGENASE, which contains iron, molybdenum and thiol groups, operates in an aqueous environment. Many attempts have been made to produce chemical models for nitrogenase based on the above knowledge and recently Schrauzer and co-workers have described dinitrogen-reducing systems of this type[1,2] but they use high pressures of dinitrogen (135 atm) and obtain only 3 to 5 μmol. of ammonia from mmol quantities of reagents[2] (see Table 1, example 1).

When the levels of reduction are very low and other nitrogen-containing ligands are present, it is essential to use $^{15}N_2$ to confirm the reduction of dinitrogen to ammonia. We have therefore tested with $^{15}N_2$ two of Schrauzer's systems and other systems which we have developed. Our quantitative

results, some of which are negative, are given in Table 1, examples 2 to 10.

Schrauzer's system contains cysteine, iron, molybdenum and $NaBH_4$ (ref. 1) and undoubtedly gives traces of $^{15}NH_3$ from $^{15}N_2$ even at 1 atm (example 2), but not in the absence of iron (example 3). Working along parallel lines we have used 2-aminoethanethiol and sodium borohydride to develop a system which gives greatly increased yields of ammonia at pressures of 1 atm and reaction times of a few hours, that is, approaching the natural conditions (example 4).

High yields of ammonia are only obtained when iron is used together with molybdenum, but we have been able to replace the thiol by bovine serum albumin (a thiol-containing protein) and to obtain low yields of ammonia even when iron is the only added metal (compare examples 5 and 6); here molybdenum may be present at a trace level but added molybdenum alone is not effective. Low levels of dinitrogen reduction using iron complexes have been reported, but no experimental details have been given[3].

High concentration of carbon monoxide inhibits our system (example 7) as does *tris*-hydroxymethylaminomethane—a buffer substance often used in the preparation of active extracts from the natural system (example 8)—presumably because it sequesters the iron from its active role.

We have also confirmed the results of Shilov and co-workers[4] that $^{15}N_2$ is reduced to hydrazine-$^{15}N_2$ in strongly alkaline solution with molybdenum or vanadium as a catalyst (examples 9 and 10). There is thus no doubt that dinitrogen is reduced in these aqueous systems and further modification may yield useful systems for the catalytic activation of dinitrogen.

Occurrence of Biogenic Siliceous Sediments in the Atlantic Ocean

ALTHOUGH the deposition of biogenic siliceous sediments is not widespread in the modern Atlantic and Caribbean, calcareous siliceous or siliceous sediments (including cherts) are recorded at various intervals in the Mesozoic[1-7] and Tertiary sequences[1-5,7-10] of both areas. On the basis of the available data it appears that the deposition of these sediments was widespread in these areas during the Lower Tertiary and possibly the Mesozoic, and more restricted during the Upper Tertiary. In this article I describe and attempt to account for the distribution of these sediments.

There are unfortunately few data concerning either the stratigraphical or the geographical distribution of Mesozoic biogenic siliceous sediments. The discovery of radiolarian oozes and cherts at eleven localities investigated by the Deep Sea Drilling Project suggests that these sediments may have been deposited intermittently over a wide area during the Upper Jurassic[1,5,6] and Upper Cretaceous (Cenomanian to Campanian)[2-4,8].

The distribution of biogenic siliceous sediments is better documented for the Lower Tertiary (see Fig. 1). Eocene siliceous oozes and/or cherts are recorded at several widely separated localities, and in the North Atlantic the prominent and widespread reflector horizon A can at least in part be identified with Middle Eocene chert beds.

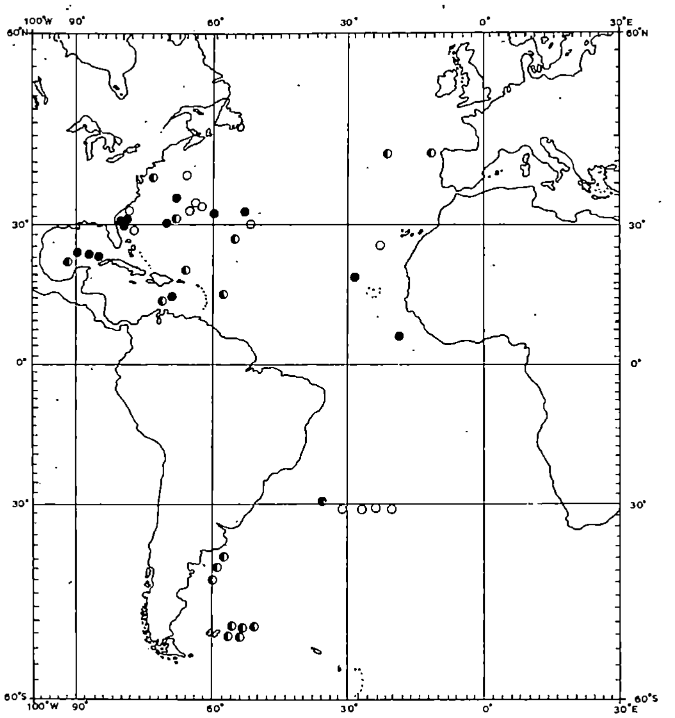

Fig. 1 The distribution of Eocene sediments in the Atlantic: filled circles represent chert, half-filled circles represent unconsolidated siliceous or calcareous siliceous ooze, and open circles represent calcareous ooze.

As a consequence of ocean floor spreading, the present location of the Palaeogene siliceous sediments does not conform with their position of deposition. Their distribution in the North Atlantic and Caribbean is evidently also unrelated to the present hydrography, biology and productivity of these areas. Fig. 2 shows the position of the Palaeogene localities plotted on Francheteau's[11] reconstruction of the Eocene Atlantic. On this chart two areas of biogenic siliceous sedimentation are defined: a southern zone situated along the western margin of the Argentine Basin, and a central equatorial zone. By analogy with the Recent oceans both areas were regions of upwelling characterized by a high production of plankton, and reflect the positions of silica belts established for the surface suspension during the Palaeogene. The southern area still lies within the major belt of silica accumulation which is associated with the Antarctic Convergence and West Wind Drift. Data presented by Saito and Funnell[12] show that this has been an area of opaline siliceous sedimentation since the Cretaceous. Although upwelling occurs at the equator in the Atlantic, the equatorial zone has no modern counterpart. In the Pacific Ocean, however, radiolarian ooze accumulates within a zone extending from 20° N to 20° S (ref. 13), which is associated with the equatorial current system. According to information published by Riedel[14] and Riedel and Funnell[15], this zone was already established during the Lower Tertiary.

The variation between the pelagic sediments associated with the Atlantic and Pacific equatorial current systems may be due to differences in their surface productivity which are caused by the higher concentration of phosphates, nitrates and silicates in the Pacific[16]. The low concentration of these nutrients in the equatorial Atlantic is directly related to the exchange of water between the North and South Atlantic, which results in their removal via the south flowing deep water of the North Atlantic[16]. On the basis of evidence obtained for Upper Cretaceous and Tertiary deep water circulation in the North Atlantic by Leg II of the Deep Sea Drilling

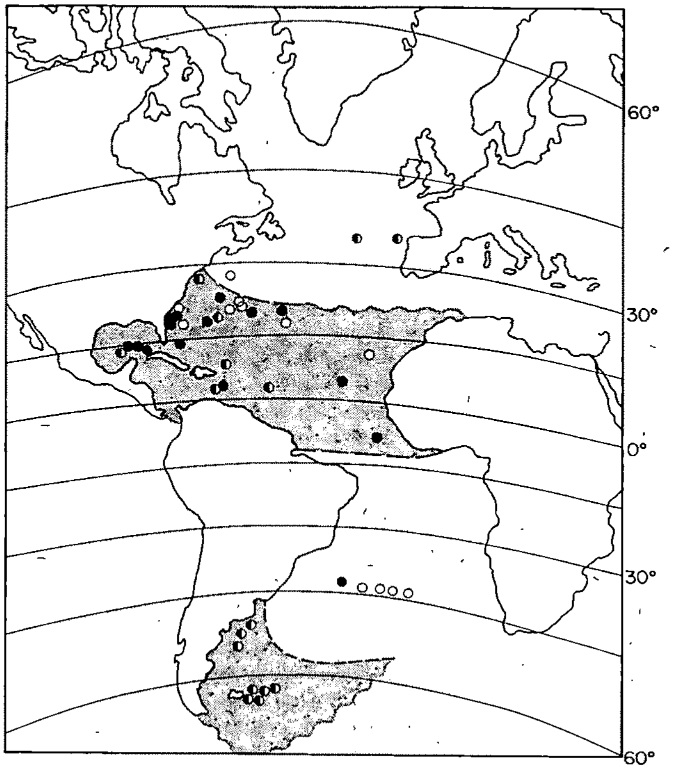

Fig. 2 The potential distribution of biogenic siliceous sediments in the Eocene Atlantic and Caribbean.

Project[5], it appears that a similar process may have operated in the Lower Tertiary Atlantic. Consequently it is unlikely that an equatorial zone of biogenic siliceous sedimentation would have developed in the Palaeogene Atlantic unless there was an influx of water rich in nutrients into this area from an outside source. Such an influx could conceivably have been achieved by the flow of Pacific equatorial water across the Isthmus of Panama via the east flowing equatorial surface countercurrent and subsurface Cromwell current (see Fig. 3). As the continuity of the present countercurrents is apparently seasonal in either ocean[17], the bulk of this flow was probably effected by the Cromwell current. At present this current is approximately 300 km wide and is symmetrical about the equator[17,18]. It occupies depths between 50 and 200 m and has a total volume transport of about 40×16^6 m^3 s^{-1} (ref. 18). A depth greater than 200 m was therefore necessary to facilitate the passage of this current across the Isthmus of Panama during the Lower Tertiary.

The distribution of calcareous and siliceous or calcareous-siliceous sediments on the Palaeogene ocean floor can be explained in terms of the circulation pattern proposed in Fig. 3. In this model the accumulation of calcareous ooze is confined essentially to areas of low productivity at the centre of the gyres. Siliceous or calcareous siliceous sedimentation occurred in regions of high productivity associated with areas of upwelling, or at the gyre margins. As in the modern oceans the accumulation of opaline silica in the bottom sediments can be attributed to the absence of a critical depth for its preservation, and to the resistance of radiolarians, silicoflagellates and the more robust species of diatoms to solution in the water column[13]. Also the increased production of carbon dioxide in sediments which underlie the fertile areas of oceans and the concomitant depression in the pH of the sea water[19,20] result in a decrease in the solubility of opaline silica and enhance the preservation of siliceous skeletal material[21] for its duration at the sediment–water interface. From the data presented in Figs. 2 and 3 it is apparent that the formation of the Eocene cherts in the North Atlantic is closely associated with the deposition of opaline silica in the Palaeogene equatorial high productivity zone. In terms of the modern Atlantic the information contained in these charts suggests that the equatorial cherts should not be encountered south of 6° N and north of 36° N.

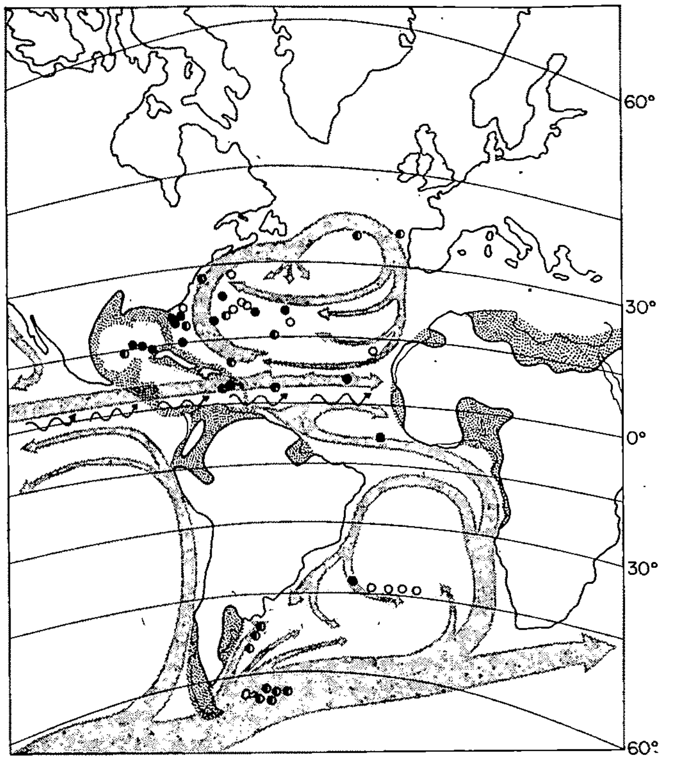

Fig. 3 Proposed circulation pattern for the Eocene Atlantic. The broad arrows represent surface currents, the sinuous arrow the Cromwell or equatorial undercurrent. The stippled regions on the continents represent shelf areas.

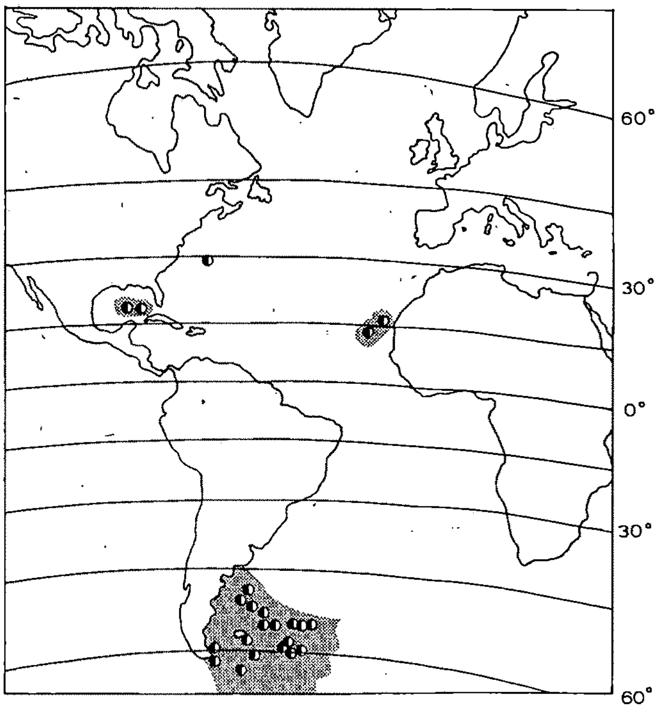

Fig. 4 The distribution of biogenic siliceous sediments in the Miocene Atlantic and Caribbean. The areas of primary production are stippled.

The equatorial zone of siliceous sedimentation had ceased to exist by the Miocene (see Fig. 4). The results of drilling and piston coring in the Atlantic and Caribbean[4,5,7,12] show that during this epoch the deposition of opaline silica occurred primarily in areas of upwelling along the western margin of the Argentine Basin and along the west coast of Africa. In the Gulf of Mexico radiolaria which may have been derived from the Pacific flourished in what is still a region of high biological productivity[22] and contributed to the formation of calcareous siliceous oozes. The distribution of biogenic siliceous sediments in the Miocene Atlantic suggests a pattern of surface and deep water circulation similar to the Recent.

This research was supported by NERC. I thank Dr Jean Francheteau for permission to publish his reconstructions of the Eocene and Miocene Atlantic, Dr John Harvey, Dr P. Liss (UEA) and Dr W. W. Hay (Illinois) for discussions, and Miss L. Bloom and Mr L. Lewis for help.

First Diagnostic Carboniferous Fossils from New Zealand

THE first New Zealand fossils indicative of Carboniferous age have been found in rocks from the South Canterbury region of the South Island. They are conodonts, accompanied by rare fish scales, and were obtained from the marble of the Kakahu inlier in a Tertiary area 10 miles south-west of Geraldine[1]: fossil sample locality No. S102/607, grid ref. 627815 (latitude 44° 09′ S, longitude 171° 04′ 30″ E).

The fossils were recovered from residues obtained by digestion of marble samples in acetic acid. The conodonts include some taxa which are known only from rocks of Pennsylvanian age, that is they are equivalent to Upper Carboniferous in North American terminology. The conodonts belong chiefly to the following genera, the time ranges of which as given by Hass[2] are appended: *Idiognathodus* Lower Pennsylvanian to Upper Pennsylvanian; *Cavusgnathus* Upper Mississippian to Lower Permian; *Gnathodus** Uppermost Devonian to Middle Permian; *Gondolella* Middle Pennsylvanian to Upper Triassic; *Hindeodella*? Lower Silurian to Upper Triassic; and *Ligonodina* Middle Ordovician to Middle Triassic.

The conodonts are opaque and whitish to dark grey in colour; many are distorted, no doubt as a result of the low grade regional metamorphism (chlorite 2 subzone) of the containing rocks. In spite of the distortion most specimens are generically determinable.

Specimens of *Idiognathodus* and *Cavusgnathus* are about equally common in the fauna as recovered. The remaining genera are represented by far fewer specimens; among these are specimens of *Gnathodus bassleri* (Harris and Hollingsworth) and *G.* cf. *roundyi* Gunnell. *Gondolella* is represented by a few incomplete specimens, mostly with unornamented platforms.

Ranges of represented genera indicate an upper Middle Pennsylvanian or lower Upper Pennsylvanian age for the Kakahu fauna. *Idiognathodus* seems to be absent from both the youngest and oldest Pennsylvanian faunas of North America; an abundance of *Idiognathodus*, as in the Kakahu fauna, is reported to be a characteristic of the Desmoinesian Stage (that is, upper Middle Pennsylvanian). *Gondolella* first appears in the Desmoinesian. On the other hand *Gnathodus bassleri* has been regarded by Lane[5] as characteristic of the Lower Pennsylvanian (Morrowan), but in Nevada it is reported by Webster[6] to range through the Derryan (that is, lower Middle Pennsylvanian). Further taxonomic work is necessary to resolve finally the question of the age of the Kakahu fauna within the Pennsylvanian.

Only indeterminate pelmatozoan remains and doubtful radiolaria had previously been recorded from the Kakahu rocks[7]; their age was therefore in doubt and suggested ages have included Lower Palaeozoic (Ordovician?)[8], early Palaeozoic[9] and late Permian, Lower Kazanian[10]. Discussing the upper Palaeozoic and lower Mesozoic rocks of South Canterbury and North Otago, Gair (in Waterhouse[11]) suggested that the chlorite 2 subzone rocks of the Kakahu district could be "at least of Lower Permian or Carboniferous age". Gair subsequently included[12] the Kakahu Marble in the Haast Schist Group which he noted as grading into sediments of Permian and Triassic age belonging to the Torlesse Group. Wright mentioned[13] having processed Kakahu limestone for conodonts in the course of his work on Ordovician conodonts, but his samples proved barren.

The significance of the Kakahu conodonts lies chiefly in the implications stemming from their Upper Carboniferous age. As the first diagnostic Carboniferous fossils found in New Zealand they fill a gap in the country's fossil record which has been considered somewhat anomalous[14]. In the light of the broad regional setting of the Kakahu inlier the conodonts indicate that accumulation in the New Zealand Geosyncline began at least as early as the Pennsylvanian, thus supporting the suggestion of Fleming[15], among others, regarding the time of initiation of sedimentation in this trough. Furthermore, the conditions of accumulation at least locally within or adjacent to the trough were suitable for the deposition of unusually pure limestones totalling some hundreds of feet in thickness. Conversely, the conodonts disprove the Lower Palaeozoic age of the Kakahu rocks and thus also the suggestion that rocks of this age outcrop east of the median tectonic line.

* Range extended by recent work of Scott and Collinson[3] and Bender and Stoppel[4].

Survival of determinable conodonts in the chlorite 2 subzone of the Kakahu inlier points to the possibility of their presence in rocks of similar metamorphic grade elsewhere; this observation could prove significant in establishing the age of parts of the Torlesse and Haast Schist Groups.

The Kakahu conodonts are the most southerly occurrence of these problematical fossils known to us. The nearest known Pennsylvanian conodonts are from south-eastern Queensland, Australia[16].

We thank G. Mansergh of the NZ Geological Survey for information regarding the Kakahu limestones and for supplying the sample which first yielded conodonts, and M. Reid, Geology Department, University of Canterbury, for processing it. Mr D. R. Gregg kindly assisted with relevant literature. The research was supported by a University of Canterbury Grants Committee research grant.

BIOLOGICAL SCIENCES

Functional Organization of Genetic Material as a Product of Molecular Evolution

MOLECULAR evolution consists of a sequence of events in which originally rare molecular mutants (DNA changes) spread into the species. Two important classes of mutations are nucleotide (or amino-acid) replacement and gene duplication.

From comparative studies of the protein sequences of related organisms, we now have some information on the rate of amino-acid substitution in evolution. The rate is different from protein to protein, but for each particular molecule, such as haemoglobin α or cytochrome c, it is remarkably uniform per year in diverse lines over geological times[1]. This constitutes very strong evidence for the hypothesis[1-3] that most nucleotide substitutions in evolution are the result of random fixation of selectively neutral or near neutral mutants. Furthermore, the rate at which neutral mutant genes are substituted in the population per generation is equal to the rate of occurrence of such mutants per gamete[5].

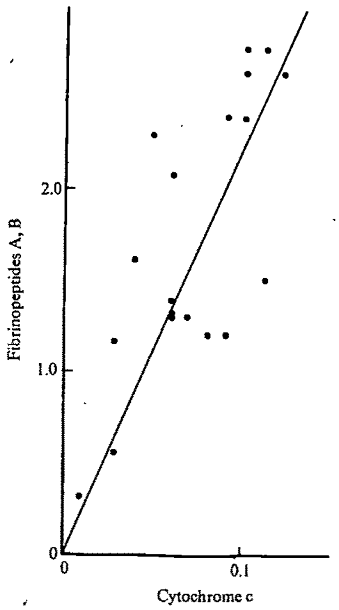

Fig. 1 The regression of the rate of amino-acid substitution of fibrinopeptides (actually their rapidly evolving parts) on that of cytochrome c. In each coordinate, the number of different amino-acid sites between two homologous proteins is expressed in terms of $-\log_e(1-p_d)$ where p_d is the fraction of differing sites. Dots represent twenty-one observed values (of which two sets of values coincide) from paired comparisons involving seven organisms (human, rhesus monkey, rabbit, dog, horse, pig and kangaroo). The estimated regression coefficient is 22.4.

There are significant differences in evolutionary rates among proteins. The highest rate (fibrinopeptides) is some 1,500 times greater than the lowest rate (histones)[4]. This means that the rate depends on the functional requirement of the molecule (refs. 1 and 3 and unpublished work of M. K. and T. O.). The greater the chance that the mutations are deleterious, the lower the evolutionary rate. The uniformity of evolutionary rate for each molecule implies that the fraction of neutral mutations among all mutations in each cistron remains constant per year.

The average rate of amino-acid substitutions estimated using nine proteins is about 1.6×10^{-9}/amino-acid site/yr[3]. If the difference of evolutionary rates among proteins is due to the difference in functional requirement rather than the difference in their mutation rate, we should expect that for any cistron the frequency of mutation at the time of occurrence is equal to that of the fibrinopeptides showing the highest substitution rate. This allows us to estimate the true mutation rate at the molecular level.

From the atlas of Dayhoff[6] we sampled seven organisms for which the complete amino-acid sequences of fibrinopeptides A, B and cytochrome c are given, from which to calculate the regression of substitution rate of the fibrinopeptides on that of cytochrome c for which the rate of substitution is well known. We therefore chose the rapidly evolving parts corresponding to the amino-acid positions four to seven in fibrinopeptide A and nine to twenty in fibrinopeptide B (alignment 9 of Dayhoff[6]). The remaining amino-acid positions not only evolve much more slowly but also show some non-randomness with respect to the pattern of substitution. We have therefore excluded these slowly evolving parts from our calculation. Fig. 1 illustrates the regression based on all the pairs of comparisons between seven organisms (human, rhesus monkey, rabbit, dog, horse, pig and kangaroo) with observed values shown by dots. The abscissa gives the number of substitutions in terms of $-\log(1-p_d)$ for cytochrome c while the ordinate gives that for fibrinopeptides, where p_d is the fraction of different amino-acids. (For the rationale of using such a logarithmic scale, see ref. 1.) The regression is about 22.4, suggesting that the true mutation rate is 22.4 times the substitution rate of cytochrome c, which is about 0.37×10^{-9}/amino-acid site/yr in mammalian evolution. The resulting mutation rate becomes

$$0.37 \times 10^{-9} \times 22.4 \approx 8.3 \times 10^{-9}$$

per amino-acid site/yr. This is roughly five times the average rate of substitutions of the nine proteins and agrees with the conclusion of Corbin and Uzzell[7], and with the conventional mutation rate per locus per generation of $10^{-5} \sim 10^{-6}$ if the average cistron codes for the protein of several hundred amino-acids long and if the average generation time is not much different from 1 yr.

If a large fraction of mutations are deleterious as discussed above, every higher organism must suffer a heavy genetic load. According to the Haldane–Muller principle[5] the mutation load of equilibrium populations is equal to one to two times the total deleterious mutation rate depending on the degree of dominance of mutations[8]. Recent investigations in *Drosophila* have shown that the detrimental mutations have a fairly high degree of dominance[9,10]. The mutation load must therefore be nearly twice the total mutation rate, although epistatic (synergistic) interaction in fitness among the loci may reduce the load somewhat[10,11].

Various species of mammals have about the same amount of DNA. The human haploid genome consists of about 3×10^9 nucleotide sites[12,13], equivalent to 10^9 amino-acid sites: thus the total mutation rate due to base replacement per genome per year amounts to

$$8.3 \times 10^{-9} \times 10^9 \approx 8$$

If the mutation rate is strictly proportional to chronological time, the rate per generation is probably twenty times this figure in man but half as large in mouse. In the main course of mammalian evolution, the average generation time was probably $2 \sim 3$ yr, so we tentatively equate 1 yr with one generation in mammals. If most of these mutations are deleterious, any mammalian species must suffer an intolerable mutation load: Muller argued[14] that the total rate for detrimental mutations in man is at most 0.5 per generation. What does such great discrepancy signify? We conclude that a large part of DNA in the genome is not essential for the life of the organisms in that base substitutions have no effects[3]. If we compare the above estimate of the total mutation rate with Muller's maximum detrimental mutation rate we are led to the conclusion that only 0.5/8 or 6% of the total DNA are as important in function as the cistrons such as those coding for cytochrome c or haemoglobins. If the estimated total mutation rate per generation is twenty times that per year and the total detrimental mutation rate is 1.0 (taking into account the "viability polygenes" of Mukai)[15], then the fraction becomes 0.6%. Although we conclude, with Muller[16], that the total number of "genes" in man is about 3×10^4, whereas he assumes a large gene size (corresponding to 30,000 amino-acids), we assume that the genes are much smaller in size (corresponding to several hundred amino-acids on average) but a large fraction of DNA is not "informational".

Mammalian DNA is about 1,000 times larger than bacterial DNA, so that the genetic material duplicated some ten times on average ($2^{10} = 1{,}024$) in the course of evolution from a unicellular organism to the mammals[17]. After each fixation of duplication in the species, irrespective of whether the duplicated part is a whole chromosome or a tiny fraction, the duplicated genes must have differentiated from the original genes through nucleotide substitution. It is possible that in this process many mutations which would have been deleterious before duplication become harmless (selectively neutral) if they occurred after duplication, for one set of genes provides the essential function of the organism. The originally deleterious mutants will spread into the population by random drift, so that there will be degeneration in many duplicated genes. The possibility of DNA degeneration after gene duplication has been pointed out by Ohno *et al.*[17] and Nei[15]. The probability of such degenerated parts acquiring new functions might be quite small. Some duplicated genes will acquire new functions, establishing themselves as important genes of the organism. But mutation is a random event, so that the chance that duplicated genes will acquire a new function must be much smaller than that they will become inert. Thus, we should expect that higher organisms have much non-informational (inert) DNA in their genome.

In this case, the rate of nucleotide substitution must be very rapid within those parts, for all the mutations are neutral. We estimate this rate approximately as $1/3 \times 8.3 \times 10^{-9}$/yr/nucleotide site, which is one-third of the estimated rate per amino-acid sites in rapidly evolving portions of the fibrinopeptides. We further multiply this by 1.2 to give total nucleotide substitution rate by taking account of the synonymous mutations[19]. The resulting rate is 0.33×10^{-8}/yr/nucleotide site. This is about five times as high as the rate estimated from the average proteins.

Recent investigations using DNA hybridization techniques indicate that the differentiation of DNA in mammalian evolution is very rapid. Laird *et al.*[20] estimated that the rate of DNA evolution is about three times as fast in artiodactyls and thirty times in rodents as the corresponding rate inferred from haemoglobins. Walker[21] estimated that the differentiation of DNA of rodents is fifteen times as fast as that of known proteins. It is possible that the evolutionary rate of total DNA is more nearly proportional to generations rather than to chronological time. More recently, Kohn[22], who has summarized these results, emphasizes that the substitution rate in DNA of mammalian genome is proportional to generations. He concludes that the number of nucleotide substitutions in non-repeated DNA is roughly five per genome per generation, and the total rate of substitutions is probably two to four times greater. It is interesting that his figure is roughly equal to our estimate, that is, eight substitutions per genome per year.

Toxicity of the Photoisomers of Cyclodiene Insecticides to Freshwater Animals

SUNLIGHT and ultraviolet light convert aldrin, dieldrin and heptachlor to their corresponding isomers, photoaldrin, photodieldrin and photoheptachlor respectively, which are more toxic to mosquito larvae and housefly adults[1-3]. In these insects the onset of toxic symptoms is much faster with the photoisomers than the parent compounds and has been assumed to be due to their rapid oxidative dehydrochlorination to lipophilic ketones[3,4]. The effect of photoisomerization of isodrin is opposite to that seen with other photoisomers. Photoisodrin, because of its rapid detoxification, is far less toxic than isodrin to these two insects[4,5].

Table 1 Toxicity of Cyclodienes and their Photoisomers to Some Freshwater Animals

Insecticide	LD$_{50}$ (p.p.m.)* Bluegills	Minnows	*Asillus*	Mosquitoes†
Aldrin	0.26	—	0.08	0.003
Photoaldrin	0.09	—	0.04	0.0005
Dieldrin	0.17	0.024	—	0.006
Photodieldrin	0.03	0.010	—	0.003
Heptachlor	—	0.013	0.10	0.005

Isodrin	0.012	—	—	0.019
Photoisodrin	0.025	—	—	0.058
Endrin	0.010	—	—	0.017

* Mortalities recorded after 24 h.

† Data from refs. 1–3 for *Aedes aegypti* larvae.

The toxicity of all these photoisomers to freshwater animals which constitute food chains has not been reported. Because cyclodiene insecticides have been used extensively, the hazards of their persisting residues may be magnified by concentration of the lipophilic metabolites of their photoconversion products in food chains (Georgacakis and Khan, unpublished work). We report here the results of a preliminary investigation on the toxicity of these photoisomers to some freshwater animals.

We used animals collected from natural conditions or purchased from local suppliers. The fish were acclimated at 65° F in an environmental room for at least 5 days in mixtures of habitat water and distilled water in the following respective proportions: 2 : 1, 1 : 2, 1 : 8, and distilled water only. The distilled water was aged at this temperature for about 2 weeks with constant aeration (oxygen concentration 10 p.p.m.). Fish were exposed in 1 pint mason jars containing 200 ml. of constantly aerated water. Each jar contained no more than four fish, tadpoles or crayfish and about five replicates (twenty animals) were used for each concentration. Microcrustaceans were exposed in 25 ml. of water in plastic Petri dishes (five to ten animals per dish) with at least two replicates. Each experiment was repeated at least twice and the average values of the two used to determine LC$_{50}$ or LT$_{50}$ values[4]. Assays were performed at 65° F using the distilled water in which the fish were acclimated. Six graded concentrations (logarithmic dosages) between predetermined dosages which caused zero and 100% mortality were used to determine LC$_{50}$ values.

Table 1 shows LC$_{50}$ values of the cyclodienes and their photoisomers to fish, crustacea and insect. To the fish isodrin and endrin are the most toxic insecticides. Photoisodrin is about two times less toxic than isodrin to all these animals. Photoaldrin, photodieldrin and photoheptachlor are more toxic than their parent compounds aldrin, dieldrin and heptachlor, respectively. Photoaldrin seems to be specially toxic to mosquito larvae[1]. The onset of toxic symptoms leading to death is much faster with photoaldrin, photodieldrin and photoheptachlor than their parent compounds as judged by LT$_{50}$ values for a number of aquatic animals (Table 2). Again, photoisodrin seems to be less toxic than isodrin or endrin; tadpoles, fish, isopods and *Daphnia* are more sensitive than *Gammarus*, crayfish and plannarians. Toxicity of photodieldrin has been reported for only a few animals[6-8], where it has been found to be two to four times more toxic to rats, mice, guinea-pigs and pigeons, equally toxic to beagles and less toxic than dieldrin to the domestic fowl. To the freshwater animals tested here, however, photoaldrin, photodieldrin and photoheptachlor are more toxic than their parent compounds. Photoisodrin is less toxic than isodrin or endrin. Because the first three photoisomers can be converted to more toxic lipophilic ketones[3,4], the toxicity of these photoisomers produced by sunlight[1-3,8] or by microorganisms[9] may be magnified by the biological concentration[10] of lipophilic ketones in animal food chains. The possible hazards of such a magnification are obvious, and research on the analysis of these photoisomers and their ketones in the environment, especially in the Great Lakes region, is badly needed.

Table 2 Toxicity of Cyclodienes and their Photoisomers to Various Freshwater Animals

Drug Dependence and Phenotypic Masking in *E. coli*

STREPTOMYCIN dependent (Sm^{D}) strains of *E. coli* L1 (which has an amber mutation in the ornithine transcarbamylase gene which is streptomycin suppressible) will grow when subcultured on Sm agar (500 μg/ml.) or on 3% EtOH agar, but not on paromomycin agar (Pm) or kanamycin (Km) agar, or any mixture of two of the drugs named (Table 1)[1]. Paromomycin dependent (Pm^{D}) mutants selected on Pm agar (200 μg/ml.), however, would grow on subculture to Pm or EtOH agar, EtOH+Pm, EtOH+Km or Pm+Km drug agars; but would not grow on Sm or Km agar, or on any other drug agar which contained streptomycin. These obvious phenotypic differences between Sm^{D} and Pm^{D} mutants were eliminated if the strains were first grown on EtOH agar and then subcultured to the different drug agars, when both types of dependent mutant were found to grow on EtOH or Sm or Pm agar, or on EtOH+Pm or Pm+Km agar (Table 1). Gorini *et al.*[1] considered the latter to be the true phenotype of the strains (which after growth on EtOH agar were called Drug^{D}) which had previously been masked by Sm or Pm which had so altered the ribosomes as to mask the true properties of the cells. They called the phenomenon "phenotypic masking".

We have investigated whether strains of *E. coli* other than L1 also exhibited phenotypic masking, and if so whether the same phenotypic pattern was eventually expressed by Sm^{D} and Pm^{D} mutants of different origin. Further, because ethanol and the aminoglycosides have no chemical similarity, we were particularly interested to test whether "the mutants are equally dependent either on ethanol or streptomycin or paromomycin . . ."[1].

Initial experiments were performed with *E. coli* SD, a streptomycin dependent strain, and *E. coli* BQPD, a paromomycin dependent strain selected by plating a sensitive strain (*E. coli* BQ) on 200 μg paromomycin sulphate/ml. nutrient agar. When these strains were plated on various drug agar plates, as Gorini *et al.*[1] had done, we obtained the growth pattern given in Table 1. Unlike that of the Harvard group, our streptomycin dependent strain grew on Sm+EtOH agar, as did both the streptomycin and paromomycin dependent strains after conversion to Drug^{D} strains by growth in alcohol agar. Our result for the Sm^{D} strain SD in regard to Sm+EtOH seems quite consistent with the behaviour of both our and Gorini's Pm^{D} strains which grow on Pm+EtOH agar. Again, although derived from different parent strains, after "unmasking" both SD and PD give growth on Sm+EtOH, whereas the Gorini Drug^{D} strains did not. Our Pm^{D} strain also differed in not growing on Km+EtOH.

Table 1 Phenotypic Characterization of Streptomycin and Paromomycin Dependent Strains of *E. coli*

Drug in plating medium	Drug provided for growth before plating					
	Streptomycin strain		Paromomycin strain		Ethanol Drug^{D} strain	
	*L1 Sm^{D}	SD	*L1 Pm^{D}	PD	*(L1 Sm^{D} or Pm^{D})	(SD or PD)
None	±	±	±	±	0	0
EtOH	+	+	+	+	+	+
Sm	+	+	0	0	+	+
Sm+EtOH	0	+	0	0	0	+
Sm+Pm	0	0	0	0	0	0
Sm+Km	0	0	0	0	0	0
Pm	0	0	+	+	+	+
Pm+EtOH	0	0	+	+	+	+
Pm+Km	0	0	+	+	+	+
Km	0	0	0	0	0	0
Km+EtOH	0	0	+	0	0	0

Concentrations of drugs whenever used: ethanol, 3%; Sm, 500 μg/ml.; Pm, 200 μg/ml.; Km, 100 μg/ml.

+, Growth after 24 h; 0, no growth even after 48 h; ±, some growth after 48 h, incubation at 37° C.

* The first column of each pair records the results of Gorini *et al.*[1].

When strains are transplanted directly from Sm media to Pm media or vice versa, no growth is obtained, nor can Drug^{D} strains of either derivation be grown on mixtures of Sm and Pm, which are always lethal.

To study the ability of the different drugs to support growth, we assumed that our Drug^{D} strains were of the same genotype (which seems likely, for they exhibited identical phenotype to these drugs irrespective of origin) and evaluated the viability of Drug^{D} SD and Drug^{D} PD on various drug agars. For these experiments the strains were first grown on 3% EtOH agar for 48 h, colonies were transferred to 3% EtOH nutrient broth and further incubated at 37° C for 21 h to give liquid cultures of Drug^{D} SD and Drug^{D} PD. Ten-fold dilution series were made in nutrient broth and 0.2 ml. spread/plate (duplicate) on each of the various drug agars listed in Table 2, where the results are given.

The parent cultures were grown in EtOH broth from small inocula, so it was assumed that the maximum survival would be obtained on EtOH agar and these counts were taken to represent the true viabilities of the cultures (100% survival). For these strains Sm agar is nearly as good a recovery medium as is EtOH agar (Table 2). On the other hand, Pm agar or mixtures of Pm+EtOH or Pm+Km agar and Sm+EtOH agar supported the survival and outgrowth of about 10^{-4} to 10^{-5} less cells, while all the other drug agars tried did not permit growth of the Drug^{D} strains.

It seems clear from this and similar experiments with other drug dependent strains of *Escherichia*, *Staphylococcus*, *Proteus* and *Bacillus*, to be reported, that Drug^{D} mutants do not form "a single class in which their dependence is equally satisfied by several drugs"[1]. Differences were also obvious in colony size and morphology: the typical coliform colony was obtained on Sm agar but atypical (small and "frosted") colonies were obtained on Pm and EtOH agar.

We have confirmed the finding that Sm/Pm mixtures are only lethal if both drugs are present in concentrations at, or above, the minimum concentrations required to kill the parent sensitive strain. It seems from this that the minimum inhibitory concentration of an aminoglycoside antibiotic is the external concentration of drug required to "saturate" the internal ribosome complement of the particular strain in the prevailing environmental conditions, cation concentration in particular. Assuming that "saturation" is brought about by drug molecules actually attaching to specific sites on the ribosomes[2-4], then the addition of a second aminoglycoside would lead to "double saturation" and "double kill" in the case of a sensitive strain. A strain resistant to one, but not the other, would still be killed by the drug saturating the ribosomes (assuming that resistance in this case is by non-attachment, the specific site being unavailable).

Table 2 Survival of Drug^D Dependent Mutants (after Growth in 3% Ethanol) on Transfer to Various Drug Agar Media

Drug in plating medium	Survival (%) (taking survival on EtOH agar as 100%)	
	Drug^D SD	Drug^D PD
None	0*	0*
EtOH	100	100
Sm	80	73
Sm+EtOH	0.03	0.004
Pm	0.02	0.004
Pm+EtOH	0.03	0.002
Pm+Km	0.02	0.004

No survivors were obtained on any of the following drug agars: Sm+Pm; Sm+Km; Sm+Nm; Pm+Nm; Km; Km+EtOH; Km+Nm; Nm; Nm+EtOH.

The strains SD and PD were grown in 3% ethanol broth at 37° C for 21 h before a decimal dilution series of each was made (in drug-free broth) to 10^{-6}. Aliquots (0.2 ml.) of each dilution from 10^{-1} to 10^{-6} were plated in duplicate on each type of agar or drug agar listed (total 192 plates per strain) and colonies counted after 48 h of growth at 37° C. The concentrations of drugs in the plates were: ethanol, 3%; Sm, 100 μg/ml.; Pm, 50 μg/ml.; Km, 100 μg/ml.; Nm, 50 μg/ml.

* Some very tiny colonies were visible after 48 h of incubation.

Why then should Sm/Pm mixtures kill the dependent strains which can grow (indeed depend for their growth) on either streptomycin or paromomycin? It seems likely that there are two separate sites on the ribosome for the attachment of these drugs, for if there were a single site there would be straightforward competition for attachment and whichever became attached growth would result. It is now well known that Sm attaches to the P_{10} protein of the 30S subunit[5]. We suggest that Pm also attaches to the P_{10} protein close to the Sm site so that, when both Pm and Sm are attached, the complex so formed prevents either drug from producing the message-correction required for survival of dependent strains, e.g. suppression of the amber mutation in the OTC message of the conditionally Sm dependent strain of Gorini and Kataja[6]. This hypothesis would also explain why Gorini, Rosset and Zimmermann[1] found "by transduction mediated by bacteriophage P1 . . . that the entire complex phenotype described above is transferred in one step from a Drug^D donor to a wild type recipient on selecting for resistance to any one of the drugs to which the donor is resistant or dependent".

Cell Division after Laser Microirradiation of Mitotic Chromosomes

Mitotic chromosomes are now being studied by laser microirradiation which involves removing small areas (0.5–2 μm long) of either DNA or protein[1]. The cells are then observed in tissue culture or fixed and stained cytochemically. By these means, it has been possible to examine nucleolus production and function by selectively altering the nucleolar organizer region of chromosomes[2]. This type of investigation requires only that the cell completes mitosis and survives in interphase long enough for nucleolus formation and function to be assayed. Although much information can be gained from this type of short term experiment, there would be more scope for investigation if irradiated cells could be cultivated for long periods of time, and shown to be capable of undergoing subsequent mitoses.

Until recently it was only possible to surmise that irradiated cells could undergo additional mitoses. In previous studies of chromosome microirradiation we used primary cultures of salamander lung epithelium. These cells remain flat during mitosis permitting precise microirradiation of desired chromosome regions. By treating the cells with acridine orange solution (1–0.01 μg/ml.) for 5 min it was possible to sensitize the chromosomal DNA to intense visible laser light[3]. The cells remained viable, reforming nucleoli and nuclear membranes. We have observed many cells for as long as 3 weeks in culture, and two reached the next metaphase, although neither of them completed division. This type of investigation was particularly difficult because the time between mitosis in these cells may be several weeks. In addition, since it is a primary culture, many cells will not even go through another division.

Because of the inherent difficulties of working with primary cultures of a cell type with an erratic mitotic rate, we looked for cells with more desirous features. We wanted cells with a rapid mitotic rate, which remained flat during mitosis so that the chromosomes were continually visible, and which had relatively few large chromosomes. We found these features in an established line of cells of the rat kangaroo (*Potorous tridactylis*)[4], which have eleven chromosomes, varying from 1 to 10 μm long, a mitotic doubling time of 24 h and, like many marsupial cells, do not round up during mitosis.

We have investigated whether these cells could divide after laser-irradiation of the chromosomes. The procedures of microirradiation were similar to those described before[2,3], except that 0.001 μg/ml. of acridine orange was used instead of 0.01 μg/ml. Rat kangaroo cells seemed to respond to a slightly lower dye plus laser treatment than do the salamander cells. After two pulses of the laser with a cumulative imposed energy in the focal spot of 84 μJ, chromosomal alterations similar to those described before were produced[1-3]. The anaphase cell in Fig. 1 had been irradiated in this manner, followed by time lapse cinematography. One chromosome of each of the two groups was irradiated (the arrow indicates the lesion in one anaphase group). The additional photographs in this figure are abstracts from time lapse footage of both of the cells formed from the above anaphase cell. Twenty-six hours after irradiation, both cells underwent normal mitosis, apparently passing through G1, S, and G2, for chromosome duplication, nucleolus disappearance and spindle formation, all occurred in the usual time.

This experiment should dispel doubts that cells with microbeam irradiated chromosomes can continue to divide. It

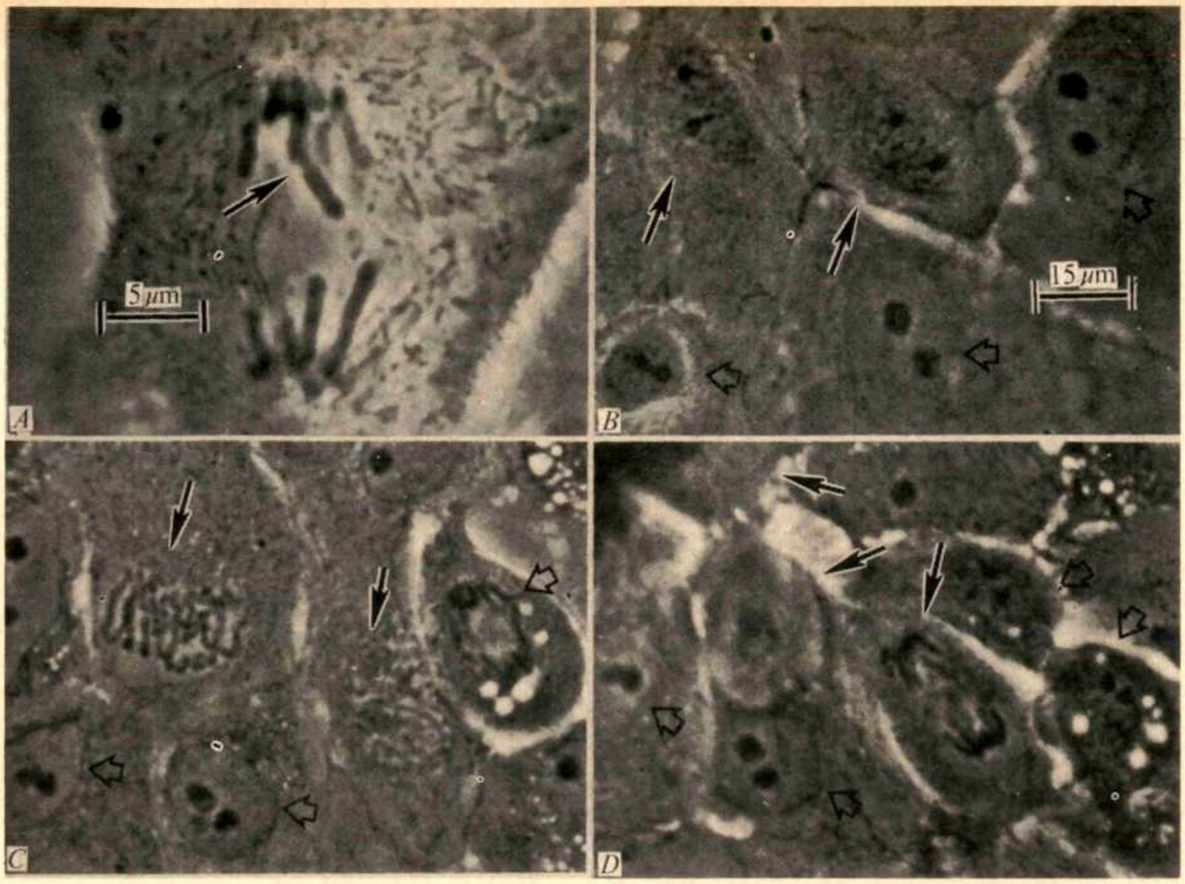

Fig. 1 Mitosis 26 h after laser microirradiation of chromosomes. *A*, Chromosome arm immediately after irradiation; the arrow indicates the altered region. *B*, 1 h after irradiation; closed arrows indicate the two daughter cells, open arrows indicate cells adjacent to irradiated cells. *C*, 25 h after irradiation; the two irradiated cells are indicated by closed arrows, one is in the middle prophase, and the other is in early prophase, one adjacent cell (open arrow) is in late anaphase. *D*, 26 h after irradiation; one of the irradiated cells has completed mitosis (closed arrows point to the two cells formed from this division), and the other irradiated cell is in late anaphase (closed arrow). Illustrations *B*, *C* and *D* are abstracts from a 16 mm time lapse film.

certainly seems feasible to establish clones from cells irradiated in this fashion. Yet the fate of the altered DNA segment of the chromosome remains to be established. It seems unlikely that the normal nucleotide sequences could be re-established in such a large segment of altered DNA.

Single-gene Heterosis in *Drosophila* revealed by Inbreeding

KIMURA and others[1-4] have suggested that most observed isoallelic variation in natural populations is maintained by mutation pressure and drift alone, and that selection is not involved. This viewpoint has been criticized[5,6], and several models[7-11] have been proposed which permit large amounts of selectively maintained polymorphism without impossibly high genetic loads. The controversy between proponents of selection and those favouring neutrality is far from resolved, and it has stimulated a great deal of work. We report here a case of conditional heterosis in *Drosophila pseudoobscura* which we feel can reasonably be attributed to the polymorphic locus being examined.

One consequence of a model proposed by Milkman[9] and elaborated by Wills, Crenshaw and Vitale[11] is that if there are many polymorphisms maintained by heterotic selection in a population, the selection coefficients associated with each of these polymorphisms will be very small. If most of the genes in the population are monomorphic, however, the selection coefficients associated with the remaining polymorphisms will be much greater. This is because the relative, rather than the absolute, heterozygosity of each organism would determine its relative fitness in the population. We reasoned that inbreeding might reveal selection coefficients associated with loci which seemed to be neutral in outbred populations.

We used a highly polymorphic population of *Drosophila pseudoobscura*, obtained in 1964 by C. W. in Strawberry Canyon, Berkeley, California, and maintained since by Dr S. Prakash. A large number of single pair matings were set up using these outbred flies, and several pure lines were obtained for each of the following electrophoretically distinguishable isoalleles: octanol dehydrogenase (ODH, autosomal, not chromosome III) 1.00 and 1.22, and esterase-5 (E-5, sex-linked) 1.00 and 1.21 (refs. 12 and 14). Both these enzymes are dimeric, and form a hybrid band in heterozygotes. The pure lines of each allelic type were pooled and maintained subsequently in mass culture to form the P_1. Single pair matings between ODH 1.00/1.00 and 1.22/1.22 gave flies all of which had the genotype 1.00/1.22. Brother–sister single pair matings were made from these cultures in turn to give the first inbred generation (I_1). Brother–sister single-pair matings were then made from the progeny of these crosses. When larvae appeared in the vials the parents were removed and their genotypes were determined (E-C vertical acrylamide gel electrophoresis). In one quarter of the vials both parents were heterozygous 1.00/1.22. These vials were retained and the remainder discarded. Flies emerging from them formed the I_2 generation, and these in turn were brother–sister mated. Cultures in which both I_2 parents were heterozygous were retained to give the I_3, and this process was continued.

Table 1 Genotypes and Numbers of Outbred and Inbred *Drosophila pseudoobscura* surviving on Stress Media

Medium	Inbreeding level			Genotype*			χ^2	P
(*a*) Flies segregating for ODH								
				1.00/1.00	1.00/1.22	1.22/1.22		
0.25 M KCl	P_1		♂♂	29 (27)	57 (54)	22 (27)	1.24	$0.75 > P > 0.5$
			♀♀	33 (27.25)	52 (54.5)	24 (27.25)	1.72	$0.5 > P > 0.25$
	I_{12}	Line A	♂♂	19 (18)	40 (36)	13 (18)	1.89	$0.5 > P > 0.25$

	I_{12}	Pooled	♀♀	52 (60.5)	129 (121)	61 (60.5)	1.73	$0.5 > P > 0.25$
(*b*) Flies segregating for E-5								
				Homozygotes	Heterozygotes			
0.25 M KCl	I_{12}		♀♀	143 (142)	141 (142)		0.01	$0.995 > P > 0.99$
3×10^{-3} M 1-octanol	I_{12}		♀♀	109 (120)	131 (120)		2.02	$0.25 > P > 0.1$

* Expected numbers are given in parentheses.

Inbreeding of the E-5 lines was carried out in a similar way, except that because the males were hemizygous brother–sister matings were retained in which the female was heterozygous 1.00/1.12 and the male was either 1.00 or 1.12. This process of inbreeding, then, gradually made more and more of the genome homozygous except for the chromosomal regions immediately surrounding the ODH or E-5 loci. Several separate inbred lines were carried for both ODH and E-5. While there was considerable lethality and infertility in the first generations of inbreeding, by the I_8 this had disappeared. The fertility of the inbred flies, as measured roughly by the proportion of successful single-pair matings, rose by the I_8 to the outbred level of 80–90%.

Pure lines were obtained from the I_{12} and maintained in mass culture. Matings were carried out between P_1 and also between I_{12} pure lines to give flies of the following genotypes: P_1 ODH 1.00/1.22; I_{12} ODH 1.00/1.22; P_1 E-5 1.00 ♂♂ and 1.00/1.12 ♀♀; P_1 E-5 1.12 ♂♂ and 1.00/1.22 ♀♀; I_{12} E-5 1.00 ♂♂ and 1.00/1.12 ♀♀; I_{12} ♂♂ and 1.00/1.12 ♀♀. Flies of each of these types were allowed to mate *inter se*. The progeny of the ODH crosses would be expected to segregate in a 1 : 2 : 1 ratio. The females of the E-5 crosses should segregate in a ratio of one 1.00/1.12 heterozygote to one homozygote for the gene carried by the male parent.

It has been demonstrated repeatedly that unusual or stress media emphasize genetic differences[15,16]. Consequently, parents of the genotypes listed in the previous paragraph were allowed to lay eggs on corn meal–molasses–agar medium to which either 0.25 M KCl or 3×10^{-3} M 1-octanol had been added. Egg-to-adult survival on both these media was poor.

The numbers of progeny flies of each genotype at the P_1 and I_{12} levels of inbreeding surviving on both KCl and octanol stress media are listed in Table 1. In most cases there was no significant deviation from Mendelian expectation. There was, however, a highly significant deviation in I_{12} ODH males surviving on the octanol medium. An excess of heterozygotes and deficiency of 1.00/1.00 homozygotes was observed in three different inbred lines of I_{12} ODH males, the pooled data yielding a χ^2 of 19.3, significant at the 0.001 level. A barely significant deviation similar to that seen in the males was observed in the females of one of the three lines.

Can this heterosis be attributed to the ODH locus itself? We believe it can. No deviation from Mendelian expectation was observed for the P_1 ODH flies on either stress medium. No deviation was observed for the I_{12} ODH flies on KCl medium, even though the genotype of their parents was identical to that of the parents of the flies raised on the octanol medium—and in most cases the parents themselves were identical, having been transferred from one stress medium to the other to continue egg-laying. The heterotic effect was thus confined specifically to the medium containing octanol, a substrate of ODH. That the octanol medium might be the cause of a generalized heterotic effect is rendered unlikely by the observation that I_{12} E-5 flies on either medium showed no excess of heterozygotes. A classical explanation for heterosis, that it is the consequence of masked subvital genes in the heterozygote, cannot be used here since survival of flies carrying all three ODH genotypes was normal on KCl medium.

The most likely explanation for the appearance of heterosis on inbreeding is that polymorphic modifiers of the ODH locus, perhaps other genes in the pathway of octanol metabolism, have been made homozygous by inbreeding. The effects of the ODH isoalleles themselves then become on inbreeding a much more important factor in the survival of the flies. The heterotic effect is far more pronounced in males than in females. Only one of the three I_{12} ODH lines showed a significant excess of heterozygotes in the females. This suggests that even after twelve generations of inbreeding modifiers sufficient to mask the heterotic effect are still segregating in the *X* chromosomes of two of the lines. Further inbreeding should clarify this point.

The use of specific stress media to detect selectional differences in highly inbred flies will, we hope, prove to be a general method for examining whether other polymorphisms are selectively neutral. Selection coefficients, though not heterosis, associated with the alcohol dehydrogenase locus of *D. melanogaster* have been detected by Gibson using a medium containing ethanol[13]. It is important to emphasize that the observed heterosis is conditional; that is, it is dependent on the particular environment. In Strawberry Canyon the ODH 1.22 allele is at a frequency of 0.023[14]. Though we have yet to determine if long-chain alcohols other than octanol produce effects on flies segregating for the ODH locus similar to those described here, one might speculate that large amounts of long chain alcohols are formed by fermentation in only a small proportion of the food supplies on which the larvae habitually grow. Selection for heterozygotes would thus only occur in a small fraction of the broods.

There are some similarities between the conditional heterosis at the ODH locus and that detected in sickle cell anaemia heterozygotes in man[17]. In the latter case, however, the heterotic effect is large enough to be observed in normally outbred humans, and one homozygote is a semi-lethal. Homozygotes for either ODH allele survive perfectly well when there is no octanol in the medium, so that ODH polymorphism imposes a far smaller genetic load on the population than does sickle cell anaemia—a load which might fall effectively to zero under laboratory conditions. Polymorphisms of the ODH type could, if numerous, permit the concealment of large amounts of genetic variability without large genetic loads. Homozygosity for these genes would not confer any great disadvantage on the organism but heterozygosity for them would, under some conditions, confer a slight advantage. How large this class of polymorphisms is remains to be seen.

We thank Mrs Elizabeth Kidder and Mr James Salzer for technical assistance, Dr S. Prakash for the flies and Dr Peter Carlson for valuable discussions. This work was supported by a grant from the US National Institutes of Health.

Survival of Mouse Embryos after Freezing and Thawing

COMPARED with the successful storage of spermatozoa and other tissue cells at sub-zero temperatures, attempts to preserve frozen mammalian eggs have been disappointing (reviewed in refs. 1 and 2), although a few pregnancies have resulted from the transfer of previously frozen fertilized rabbit eggs[3] and unfertilized mouse eggs[4] to recipient foster mothers. I now wish to describe a technique for obtaining a high proportion of viable embryos after subjecting them to sub-zero temperatures.

Random bred female albino mice (CFLP strain, Carworth Europe) 6–8 weeks old were superovulated with gonadotrophins[5]. Eight-cell embryos were flushed from the oviducts and anterior portion of the uterine horns of mated females 68–72 h later and early blastocysts were flushed from the uterine horns a further 24–28 h later. Embryos were collected in Dulbecco's phosphate buffered salt solution[6] supplemented with 0.33 mM sodium pyruvate, 5.56 mM glucose, 3 mg/ml. bovine serum albumin and 100 IU/ml. penicillin G (potassium salt). The medium had a *p*H of approximately 7.2 and an osmolarity of 287.6 ± 0.9 mosmols; it was similar in composition to that used for storage of mouse embryos at temperatures between 0° and 10° C[7]. Embryos were washed in several changes of medium (2 ml./wash) to remove debris.

Between twelve and twenty embryos were placed in 0.25 ml. of the medium in a 5 ml. test-tube and cooled to 0° C on crushed ice. Then 0.25 ml. of medium plus 15% polyvinylpyrolidine (PVP), previously cooled to 0° C, was added and 3–5 min were allowed for the mixture to equilibrate. The final concentration of PVP (7.5%) was half that used to freeze mammalian blood cells[8]. After equilibration the test-tube was placed in a mixture of acetone and dry ice at $-79°$ C for 5 min. The rate of cooling from 0° to $-79°$ C was approximately 1° C/s. The test-tube was transferred to a vacuum flask of dry ice and left for 30 min before thawing.

To thaw, the test-tube was placed in a water bath at 37° C and 1 ml. of medium, also at 37° C, was added to reduce the concentration of PVP as the medium thawed. The rate of warming to 20° C was approximately 1.4° C/s. The contents of the test-tube were emptied into a solid embryological watch-glass and embryos that looked normal were collected and washed through several changes of medium as quickly as possible because exposure to concentrations of PVP greater than 1% for prolonged periods adversely affects further development (my unpublished observations). Embryos were then transferred to a modified Krebs–Ringer bicarbonate medium[9] and cultured by the method described by Brinster[10]. Table 1 gives the combined results of four experiments which were not significantly different. Of 186 eight-cell ova initially frozen, 139 (74.7%) apparently normal embryos were recovered on thawing and ninety-six (69.1%) of these developed into blastocysts after 48 h in culture.

The combined data for two experiments with early blastocysts are given in Table 1, for again there was no significant difference. Fifty early blastocysts were frozen; thirty-four (68.0%), which were apparently normal, recovered, thirty-one (91.2%) of which expanded fully after culturing for a further 24 h at 37° C.

Although there was no significant difference between the number of normal looking eight-cell ova and early blastocysts recovered after freezing, the subsequent development of the early blastocysts in culture was better than the eight-cell ova ($\chi^2_{(1)}=8.02$; $0.01>P>0.001$).

To test further the viability of the embryos after thawing, nineteen eight-cell ova were transferred after thawing to the ampullar region of the left oviducts (six to seven per oviduct) of three F_1 hybrid females (C57Bl × CBA) on day 1 of pseudopregnancy[11] (day 1 being the day on which the vaginal plug was found). On day 18 of pregnancy two females were pregnant; the left uterine horn of one had three normal looking albino foetuses and two resorptions from the six eight-cell ova transferred, the other female had one albino foetus and three resorptions out of seven eight-cell ova transferred. Thus nine out of nineteen (47.4%) implantations and four out of nineteen (21.1%) foetuses resulted from the transfer of eight-cell ova previously frozen and thawed.

Table 1 Development *in vitro* of Mouse Embryos previously Frozen and Held for 30 min at −79° C before Thawing at 37° C

Developmental stage	No. of experiments	No. of embryos frozen	No. of embryos recovered	No. of blastocysts after culture	Blastocysts (%)
Eight-cell	4	186	139	96*	69.1
Early blastocysts	2	50	34	31†	91.2

* Cultured for 48 h after thawing.
† Cultured for 24 h after thawing.
Experiments combined as they were not significantly different.

Thirteen expanded blastocysts, obtained after freezing and thawing the early blastocysts and culturing them for a further 24 h, were transferred to the left uterine horns of two F_1 hybrid females (C57Bl × CBA) on day 3 of pseudopregnancy (six and seven per horn respectively)[12]. Six and three albino mice respectively were born to the two females. Thus nine out of thirteen (69.2%) blastocysts previously frozen developed into normal young after transfer. Again, viability after freezing and thawing was significantly greater than that of the eight-cell ova ($\chi^2_{(1)} = 8.46$; $0.01 > P > 0.001$).

These results demonstrate that mouse embryos can be frozen and thawed successfully if a suitable protective agent is added to the medium before freezing. Protective agents such as glycerol and dimethyl sulphoxide had previously been found to be toxic to embryos above 0° C[7] and I found that 'Dextran T70' (Pharmacia) and sucrose failed to protect the embryos during freezing. 'Ficoll' (Pharmacia) protected a few embryos but so far PVP has been the most effective protective agent. The blastocysts seemed to be more resistant to freezing than the eight-cell embryos, which is inconsistent with the observation[13] that rabbit blastocysts were less resistant than earlier stages to storage at about 10° C.

With the perfection of this technique, the storage of mutant strains of mice not in current use but of potential interest could be possible. At the appropriate time the stored embryos could be transferred to foster mothers and the resulting offspring used to re-establish the mutant strain. The application of this technique to the large domestic animals could facilitate the dissemination of stock of good genetic background and possibly shorten the generation time for progeny testing. Low temperature storage combined with the sexing of embryos, when this method is developed, would have tremendous scope for the improvement of livestock in the future.

I thank Professor C. R. Austin for advice and for facilities. This work was conducted while I was recipient of a Beit Memorial research fellowship and was supported by a grant from the Medical Research Council.

Unsuccessful Attempts to Transfer Morphine Tolerance and Passive Avoidance by Brain Extracts

SEVERAL positive and negative reports have been reviewed recently[1,2] on the possibility of transferring acquired behaviour from animal to animal by injecting brain extract from a trained donor into an untrained recipient. We were interested in the possibility of transferring morphine tolerance from rats to mice, as reported by Ungar and Galvan[3]. We failed to replicate this finding, as had other investigators[4,5]. Nevertheless, we felt it worthwhile to search for the appropriate conditions and chose Ungar's simpler system of "fear transfer" as a model[6,7]. Here rats are overtrained (by means of foot shock) to avoid entering a black box; recipient mice are then tested in the same box. To enable us to follow accurately the published procedures one of us (A. G.) spent a few days in Ungar's laboratory. In the next 3 months we carried out eighteen unsuccessful experiments with 125 donor rats and 383 recipient and saline control mice. We then did a blind test in our mice using control and trained donor extracts provided by Dr Ungar. Next, we sent 100 of our mice to Houston, for testing as recipients concurrently with the local strain. Finally, we selected, from all our experiments, those mice (of both sexes) which seemed to avoid the black box more often after receiving the extracts. These animals were bred and the offspring were tested as recipients. We hoped to select for recipient capability that might be under genetic influence. The results of all these experiments were negative or equivocal.

For tolerance the procedures of Ungar and Galvan[3] were followed closely. Sprague–Dawley male rats (200–250 g) were made tolerant by three daily subcutaneous injections of morphine sulphate, starting with 10 mg/kg (in terms of the free base) and increasing to 100 mg/kg after 14 days. Rats were decapitated 12 h later, and brains were removed quickly and stored frozen on dry ice until required.

Recipients were thirty-four Swiss–Webster male mice (25–35 g), screened a week earlier as follows. First, they were tested for response on a 56° C hot plate[8]; all reacted within 30 s, after which morphine sulphate was given (35 mg/kg of free base intraperitoneally). After 30 min the mice were re-tested on the hot plate; two which reacted within 30 s were discarded. Morphine-induced running activity was also measured in special counter cages[9]. From the 4 h cumulative record, the sixteen most active runners were ranked, alternate mice being assigned to two groups. A coin was tossed to decide which group would receive physiological saline and which tolerant rat brain extracts. These solutions were administered intraperitoneally, and 24 h later mice were tested as in the screening procedure.

For passive avoidance procedures were as described by Ungar *et al.*[6,7] except as noted. The apparatus for training and testing consisted of a white 'Lucite' box (30×30×15 cm high) with transparent cover, connected by a small black passageway to a black 'Lucite' box (25×10×15 cm high) with an opaque cover and a grid floor which could be electrified (80 V, 60 Hz). The apparatus was built to Ungar's specifications, except that his second white box was omitted. Sprague–Dawley male rats were placed in the white box and shocked for 5 s when they ran into the dark box, the passageway being closed by a barrier during the shock period. A rat which did not run back into the white box after being shocked was placed there by hand. After the first shock the rat had to be forced into the black box each time. A waiting period of 10 s separated successive trials. Five trials constituted a session, and sessions were repeated daily for 6 days. After the first few trials, most rats displayed obvious signs of apprehension (defaecation, urination, attempts to jump out, crouching in a corner) when placed in the white box. Some learned to position their paws on the grid so as to avoid shock, but the experimenter overcame this by grasping the tail (protruding under the passageway barrier) and jiggling the rat back and forth. In two experiments donors were subjected to only a single training session before decapitation 5 days later.

Recipients were Swiss–Webster mice, usually males (25–30 g). The only modification in the apparatus was the introduction of a barrier containing a mouse hole (2.7 cm diameter semicircle) in the passageway. Two measures were used: latency time to enter the hole initially; and black box time, the total spent in the black box (all four paws inside the mouse hole) in a 180 s test period.

Recipient mice received a familiarization session (day 1), then a screening session (day 2). For the 211 mice subsequently given saline or brain extracts from untrained donors, the mean values and standard errors on day 2 were: latency, 14.6±0.7 s; black box time, 138.9±1.4 s. The corresponding values for 172 mice later given brain extracts from trained donors were: 12.6±0.6 and 139.2±1.5. We rarely found mice with black box times less than 90 s, so few were excluded. Injections (intraperitoneal) were given on day 3, testing sessions were conducted on days 4 and 5. The mice (usually twenty-four) were coded, ranked in order of day 2 latency, and assigned alternately to the treatments. All testing was "blind".

Donors were decapitated 1–2 h after their last training session. Brains were cut sagittally, sandwiched between pieces of dry ice within 30 s, and sometimes kept overnight at −20° C. Subsequently the temperature was kept below 5° C. The brains were homogenized in cold distilled water (6 ml./brain) at 850 r.p.m. using a 'Teflon' pestle. The homogenate was adjusted to *p*H 7.5 with NaOH and HCl, then dialysed against 20 volumes of distilled water for 24 or 48 h. In the morphine tolerance experiment the homogenate was centrifuged at 26,000*g* for 2 h and the supernatant was dialysed for 24 h. The dialysate was lyophilized, dissolved in distilled water (1 ml./brain) and stored at −20° C until use. Each recipient was given 0.5 ml. intraperitoneally. Sometimes, instead of dialysis, the homogenate was stirred on a magnetic mixer at 5° C or at room temperature, then centrifuged (39,000*g*, 30 min), and the supernatant was used directly or after lyophilizing.

The attempt to transfer tolerance to mice using tolerant rat brain extracts is summarized in Table 1. The day after receiving physiological saline or tolerant rat brain extract, all the mice reacted on the hot plate. After the test injection of morphine all displayed good analgesia, with one exception. An occasional morphine-treated mouse will react on the hot plate*, so no significance can be attached to this solitary result. There was a tendency in both groups towards enhanced morphine-induced running; the mean increase was 12% in the control group and 20% in the extract-treated group. Our testing procedure (hot-plate analgesia and running activity) differed from that used in Ungar's laboratory[3,10] (tail clip analgesia), and our standard test dose of morphine (35mg/kg) was much larger than theirs (4.5 mg/kg). We have shown[9], however, that after mice are made tolerant by repeated injections, this dose fails to produce analgesia (hot plate), and opiate-induced running is substantially reduced or absent. Thus, in this experiment, no tolerance was observed in the recipient mice.

Table 1 Testing of Recipient Mice for Tolerance to Morphine

	Reaction time on hot plate (s)		Running activity (counts in 4 h)		
	Before morphine	30 min after morphine	7 days before at screening	After morphine	Change (%)

Control mice received physiological saline, extract mice received brain extract from tolerant rats 24 h earlier, one half brain equivalent per mouse. Morphine sulphate (35 mg/kg free base) was given intraperitoneally. NR: no reaction in 30 s.

Two experiments were carried out with mice as both donors and recipients. Donors were made tolerant to increasing doses of the morphine congener, levorphanol tartrate (20–100 mg/kg). Controls received sodium tartrate on the same schedule. In the first experiment, many of the recipients died within a few hours of intraperitoneal administration of either type of extract equivalent to one to two mouse brains. In the second experiment, in which recipients received material equivalent to half a mouse brain, the animals survived. Three hours later, all fifteen controls and all thirteen which had received tolerant extracts reacted within 30 s on the hot plate. They were then given levorphanol tartrate (10 mg/kg of free base) intraperitoneally and were tested after 30 min. Two mice in each group reacted within 30 s; the rest showed typical opiate analgesia. Repeated testing after 1 and 2 h revealed no difference between the groups in the rate of disappearance of analgesia. In agreement with Ungar and Galvan[3], therefore, we could not transfer opiate tolerance from mouse to mouse.

Preliminary to our attempts to transfer passive avoidance, we first examined the effect of foot shock on the subsequent behaviour of twenty-six untreated male mice. On day 1, half of these were individually familiarized with the apparatus for 180 s each, while the other half received shock (up to 5 s) as soon as they ran into the black box. Nearly all ran out again immediately after receiving only 1–2 s of shock. On day 2 all mice were tested again with no shock. On day 3 the unshocked animals were given saline injections and tested again on day 4. The behaviour of the unshocked mice was typical of that observed in all experiments (Table 2). On their first encounter with the apparatus there was much individual variability;

---

* In the screening procedure for this experiment, as noted earlier, two mice out of the thirty-four failed to display analgesia after a morphine injection.

mean latency was 61 s (s.d. 52; range 8–180, with one mouse not entering the black box at all). On day 2 the mean latency had decreased to 16 s and the responses were more consistent (s.d. 16, range 4–64). The same trend continued on day 4. Black box times showed similar effects, with means increasing from 88 to 146 to 157 and s.d. decreasing from 41 to 23 and 24. Thus, after the familiarization day, both latency and black-box times were predictable and reliable, with no remarkable effect from the inert injection on day 3. In contrast, the shocked mice showed a mean latency increase from 33 s to 139 s, and nine of them avoided the black box altogether. The differences between the unshocked and shocked groups were highly significant (t test, two-sample rank test, binomial sign test).

In the transfer experiments there were no evident differences among the several procedures used, so data are pooled for presentation. To minimize variability, each mouse was used as its own control. The results are expressed as a frequency distribution of differences in latencies (Fig. 1) or black-box times (Fig. 2) between day 2 and day 4 and between day 2 and day 5. The null hypothesis predicts a mean difference of zero, but in the controls there is a consistent decrease in latency and increase in black box time, which presumably reflects greater familiarity with the box. For the 211 control mice and the 172 mice receiving extracts from trained donors the frequency distributions are virtually identical.

In spite of negative results for most of the animals, in some mice one can find possible indications of a weak effect in the relevant direction. Latency results on day 4 show only two of the controls having an increase greater than 100 s, whereas seven of the extract recipients fall into this category. On day 5 the corresponding figures are eight and ten. For black box time on day 4, only two control mice but six extract-treated animals show reductions of more than 100 s. On day 5 the corresponding figures were six and twelve.

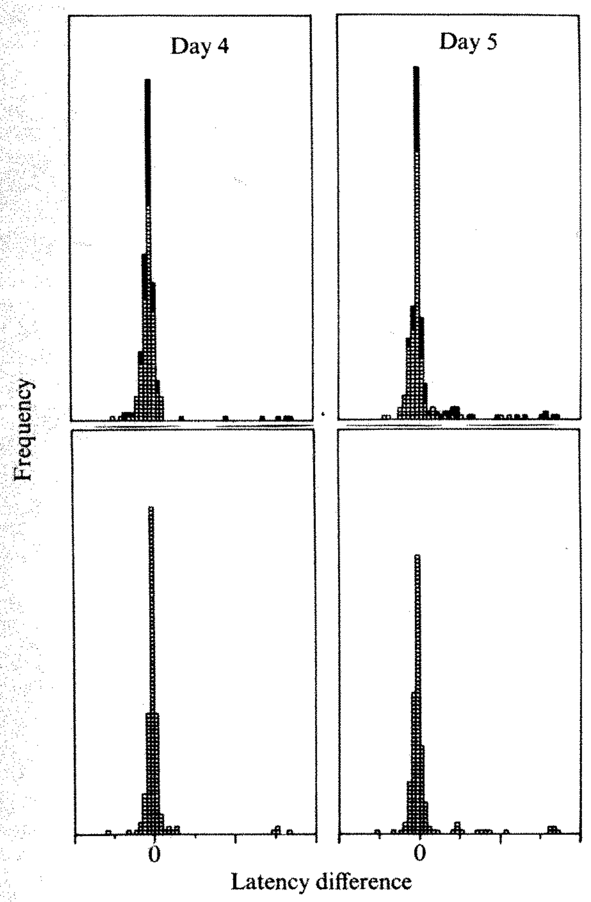

Fig. 1 Frequency distribution of latency differences in eighteen experiments. Ninety-three trained donor rats; seventy-three untrained donor rats; 146 saline injected recipient mice; sixty-five recipient mice receiving brain extract from untrained donor rats; 172 recipient mice receiving extract from trained donor rats. Each box represents one mouse. In upper graphs open boxes are saline controls, black boxes are untrained brain extract controls. In lower graphs all mice received extract from trained donors. Horizontal axis shows change in latency for each mouse from day 2 (screening) to day 4 (or day 5). Each large scale mark represents 100 s; thus the range shown is from −100 to +200 s.

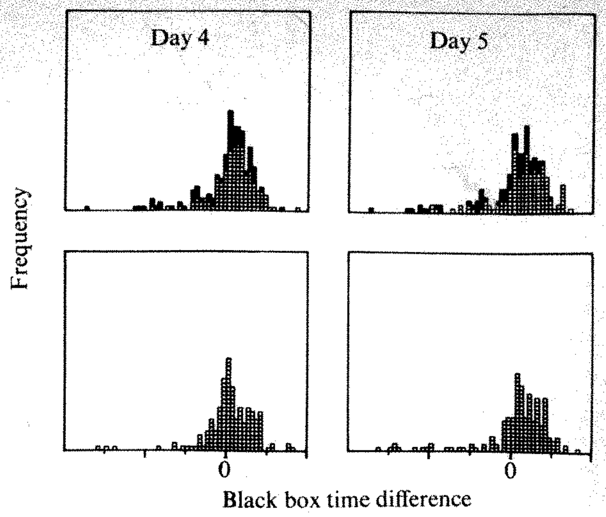

Fig. 2 Frequency distribution of black box time differences in eighteen experiments. Symbols and scales as in Fig. 1.

Table 2 Effects of Shock and No Shock on Latency and Black Box Time

	Latency (s)			Black box time (s)		
	Median	Mean	s.d.	Median	Mean	s.d.
Unshocked group (N=13)						
Day 1	53	61	52	98	88	41
Day 2	11	16	16	150	146	23
Day 3		Injection			Injection	
Day 4	8	12	11	166	157	24
Shocked group (N=13)						
Day 1 (shocked)	30	33	23	–*	–*	–*
Day 2	180	139	70	0	34	61

* No data because mice ran out immediately on being shocked.

Mice were treated as described in the text. Foot shock (80 V a.c.) was administered on day 1 as soon as a mouse entered the black box. Unshocked mice were given a saline injection intraperitoneally on day 3 and retested on day 4.

To test the hypothesis that a few mice were sensitive to the effect of the extract, we examined the extremes of the frequency distributions. In each experiment we noted which three mice had the longest latencies, and which three had the shortest black box times. The results were: latency day 4, twenty-six extract and twenty-four control; latency day 5, twenty-eight and twenty-three; black box time day 4, twenty-one and twenty-eight; black box time day 5, twenty-seven and twenty-two†. There is a very small non-significant trend in the predicted direction.

Dr Ungar kindly supplied us with some of his extract from trained and untrained donors to test in our laboratory. For this experiment fifty-two mice were familiarized, screened, ranked and assigned to treatments as described earlier. One

† The totals sometimes exceed 3×16=48 because if the third-ranking mouse was one of a tied pair, both members of the pair were included.

of us injected the animals, another did all the testing "blind". At the screening session, the mean latencies were: group A = 12 s, group B = 12 s; mean black box times: group A = 145 s, group B = 142 s. Injection dose was 1 g rat brain equivalent/mouse, on Dr Ungar's recommendation (Table 3). In both groups the medians and means indicate a skewing of the frequency distributions towards longer latencies and shorter black box times. The only suggestion of a difference between the groups was at 24 h, where there was a slight (but not significant) preponderance of longer latencies and shorter black box times in group B.

Table 3 Effect of Extract from Untrained and Trained Donors

Test time after injection (h)		Latency change (s)			Black box time change (s)		
		Median	Mean	s.d.	Median	Mean	s.d.
6	*A*	−4	−1	7	16	5	42
	B	0	5	19	4	1	27
24	*A*	0	13	39	3	−1	41
	B	2	30	55	10	−10	57
48	*A*	4	27	59	0	−13	62
	B	3	34	67	12	−11	70
			Extreme latency change (> 50 s)			Extreme change in black box time (> 50s)	
6	*A*		0			2	
	B		2			1	
24	*A*		1			1	
	B		5			4	
48	*A*		3			3	
	B		4			4	

Extracts were supplied by Dr Ungar and tested as described in text. Data in the upper part of the table are changes in latency and black box time (result at time of testing less that at screening session), computed for each individual mouse. Medians, means, and standard deviations are for the set of individual mouse differences. Group A received extracts from untrained donors, group B from trained donors. There were twenty in each group. Data in lower part of table are numbers of mice displaying extreme behaviour in the predicted direction (increased latency, decreased black box time).

When we did not obtain positive results with Ungar's extracts in our laboratory, we concluded that our mouse strain rather than our technique of preparing extracts might be at fault. With Dr Ungar's cooperation, we shipped 100 males of our strain (Bioscience Labs, Inc.) to Houston, where they were tested at various doses of extract along with his Texas inbred strain. Because we were unable to agree with Dr Ungar on the interpretation of the results they are not included here but will presumably be published independently by him.

Finally, although most mice were not good recipients, what few weak effects had been observed might be attributable to a small fraction of the mice having recipient capacity. A transfer factor might be destroyed enzymatically in most recipients, but not in genetic variants. Accordingly, we saved those males and females which showed the greatest prolongations of latency or reductions in black box time in all sixteen experiments. These were bred, and eventually the F1 generation was tested, by randomly assigning littermates to the comparison groups. At screening, results were: mean latencies 12 (s.d. 5) and 11 (s.d. 5), black box times 134 (s.d. 24) and 132 (s.d. 27), for the groups that were to receive extract from untrained and trained donors, respectively. There were no significant differences between the two extracts (Table 4).

We should not dismiss the possibility that acquired behaviour, such as conditioned dark avoidance, can be transferred by brain extracts merely because the proposed mechanisms[11,12] seem fanciful, especially since confirmatory reports have been published from several laboratories[13-15]. On the other hand, our rather exhaustive but unsuccessful attempts to replicate the findings suggest, at the least, that the precise conditions for successful transfer will have to be worked out and defined much more carefully than heretofore if this phenomenon is to meet the test of reproducibility. As matters stand now, it would be more useful for the proponents to establish rigorously and in great detail the conditions for reliably transferring one kind of behaviour in a single species, than to publish marginally successful experiments using different paradigms in a variety of animals.

Table 4 Testing of F_1 Offspring of Best Recipients

Test time after injection (h)		Latency change (s)			Black box time change (s)		
		Median	Mean	s.d.	Median	Mean	s.d.
24	Untrained extract	0	0	7	−2	−10	43
	Trained extract	−2	−1	6	16	11	27
48	Untrained extract	−2	−1	8	21	18	18
	Trained extract	−2	−2	6	10	5	37

Offspring of best recipients from sixteen experiments. Five litters were screened, then littermates assigned randomly to the two groups. $N = 14$ for each group. Extracts from untrained and trained donors were prepared as described, and injected.

We thank Dr George Ungar for hospitality and cooperation, and Barbara A. Judson, Valerie Cunningham, Dennis Uyemura and Ellen Fitzsimmons for technical assistance. This investigation was supported by a grant from the US National Institute of Mental Health.

Formation of Cerebrospinal Fluid in Spinal Subarachnoid Space

IT has been generally accepted that the fluid bathing the central nervous system is produced within the cerebral ventricular system, although some people have favoured extraventricular formation[1-3] as well. Some considered that another site of formation was the spinal subarachnoid space[4,5] (Fig. 1), but others disagreed[6,7].

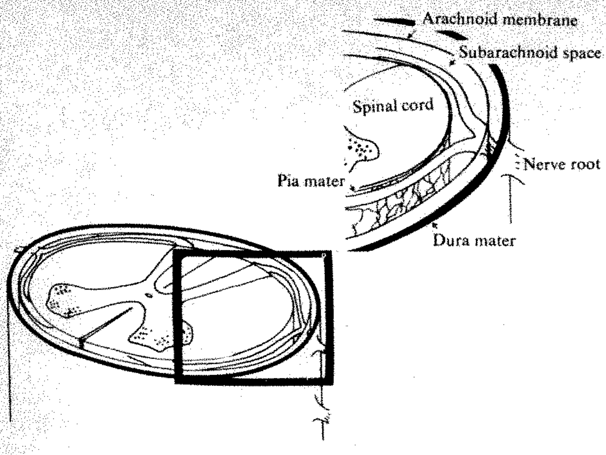

Fig. 1 Section through spinal cord showing position of subarachnoid space.

We have now investigated this problem, performing the inulin perfusion through the spinal subarachnoid space of mongrel dogs (12–15 kg). For anaesthesia 30 mg of pentobarbital/kg body weight was given intraperitoneally and each dog was endotracheally intubated and connected to a respirator after receiving 20 mg of succinylcholine intramuscularly to keep it still.

The dog was fixed in a prone position with the head slightly elevated. Laminectomies were performed over the cauda equina and upper cervical region. The lumbosacral subarachnoid space was punctured with an Argyle 'Medicut' cannula. which was connected to an inflow tubing through which passed an artificial CSF containing 25 mg% of inulin at a rate of about 0.3 ml./min. An Argyle cannula was also inserted into the upper cervical subarachnoid space and connected with outflow tubing which could be raised or lowered to change the CSF pressure during the experiment. No CSF was allowed to leak in and around the puncture sites.

Outflow samples were obtained every 10 min, after a steady state had been reached, at different pressures. These were analysed by the resorcinol recovery method for inulin concentration determination.

Every experiment was followed by autopsy to see whether the perfusion fluid was limited in the spinal subarachnoid space and whether it was bathing the entire system. This was confirmed by perfusing methylene blue dye in the same condition immediately after the final sample had been collected. We found no mixing of subarachnoid fluid between intracranial and spinal subarachnoid spaces.

CSF formation rate was calculated by the method of Heisey *et al.*[1], combining the effects of hydrostatic pressure on outflow–inflow differences and on clearance of inulin, which measured only bulk absorption. The notation to be used in the following description is that of Heisey *et al.* The use of clearance of inulin as a measure of absorption was based on the assumption that the diffusive absorption of inulin was negligible. Therefore the relation between inulin clearance and bulk absorption can be written

$$\dot{V}_a = C_{in} \qquad (1)$$

where $\dot{V}_a$ is the rate of bulk absorption in ml./min; C_{in} is the steady state clearance in ml./min of inulin out of the perfusion system per unit concentration; $C_{in} = \dot{V}_i C_i - \dot{V}_o C_o / \bar{C}$; $\bar{C}$ is mean concentration in the system $= C_o + 0.37\ (C_i - C_o)$; $\dot{V}_i$ and $\dot{V}_o$ are the influx and efflux flow rates in ml./min, and C_i and C_o are the concentrations of inulin in the influx and efflux respectively.

When the outflow volume was equal to the inflow, the rate of absorption was equal to the CSF production rate ($\dot{V}_f$). Therefore, the relation between outflow–inflow difference, formation and absorption of CSF can be expressed as

$$\dot{V}_o - \dot{V}_i = \dot{V}_f - \dot{V}_a \qquad (2)$$

Substituting $\dot{V}_o - \dot{V}_i$ for $O - I$ and $\dot{V}_a$ for C_{in}, from equation (1), the formation rate can be calculated by the following equation.

$$\dot{V}_f = (O - I) + \dot{V}_a \qquad (3)$$

The outflow rates are therefore less than inflow rates, and more fluid is absorbed than is produced. The outflow rate increased as the outlet was lowered and decreased when it was raised. In spinal subarachnoid perfusion, expressions for $O - I$, $\dot{V}_a$ and $\dot{V}_f$ are:

$$O - I = 0.0206\ (\pm 0.00165) - 0.348 \times 10^{-3}\ \text{CSFP ml./min}$$

$$\dot{V}_a \ = 0.0005\ (\pm 0.00005) + 0.320 \times 10^{-3}\ \text{CSFP ml./min}$$

and

$$\dot{V}_f \ = 0.0201\ (\pm 0.00244) - 0.288 \times 10^{-4}\ \text{CSFP ml./min} \quad (n = 41)$$

where CSFP stands for cerebrospinal fluid pressure when zero pressure was taken at the level of the spinal cord during the perfusion. From these equations the production rate is 0.018 (±0.002) ml./min when outflow is equal to inflow rates at the pressure of 59 mm of water.

Although the results give no data as to the actual site or mechanism of the formation of fluid in the space, these experiments have conclusively demonstrated that CSF is being formed in the spinal subarachnoid space and that it is important for this extraventricular production of fluid to be recognized, particularly when one considers the problem of the CSF circulation.

Reflecting Spheres in the Eyes of Weakfishes (Sciaenidae)

A REFLECTING layer or tapetum lucidum occurs in the eyes of many fishes; in teleosts, it lies in the pigment epithelium[1]. The reflecting material is usually considered to be guanine, but in weakfishes or seatrouts (Sciaenidae) it is a lipid[2,3]. We have been able to characterize the lipid material.

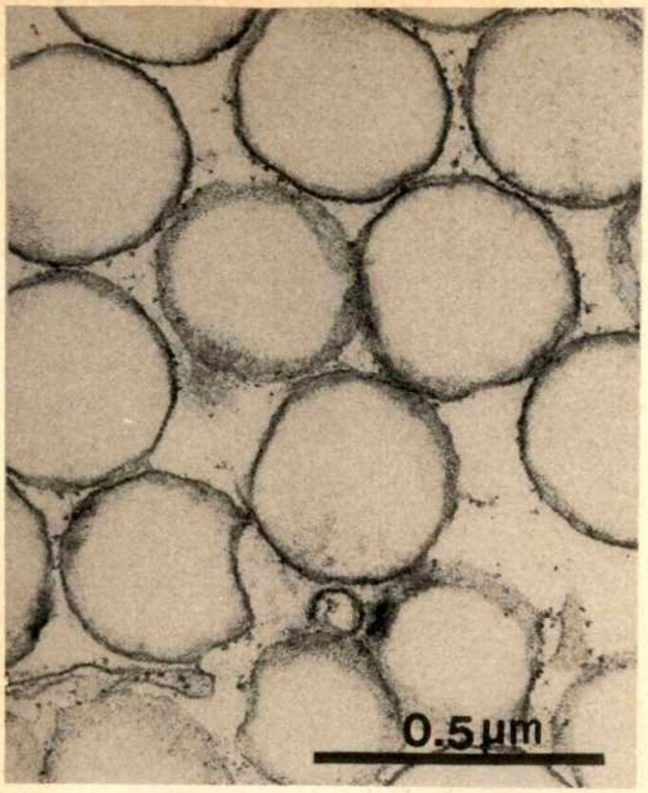

Fig. 1 Lipid spheres in a pigment epithelial cell of the sandtrout (*C. arenarius*) fixed in 3% glutaraldehyde in a 0.1% phosphate buffer, postfixed in 2% osmium tetroxide in the same buffer. This fixation technique does not preserve all the contained lipid, but does define the size and shape of the spheres. The boundary layer is associated with some of the contained lipid and appears to be thicker than an ordinary cytomembrane. Other fixation techniques retain the lipids[2].

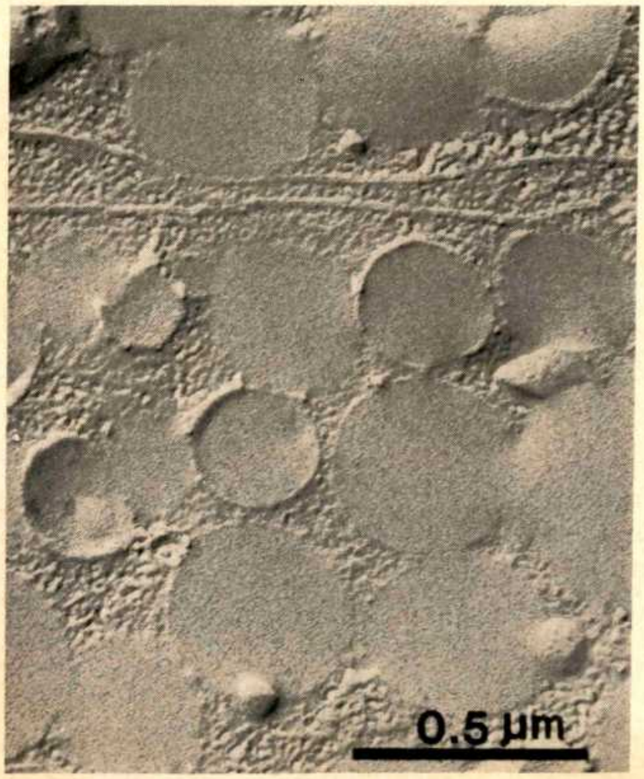

Fig. 2 Lipid spheres from the pigment epithelial cells of the sandtrout (*C. arenarius*) as they appear in freeze-etch preparations. Note the plasma membranes of two pigment epithelial cells and compare these cytomembranes with the surface of the lipid spheres.

The pigment epithelial cells of seatrouts (*Cynoscion arenarius* and *C. nebulosus*) are densely packed with small spheres, about 0.4 µm in diameter (Fig. 1), which are present throughout the length of the cell, but most abundant distal (that is, vitread) to the nucleus. There are about fifteen spheres per µm^3. The cytoplasm in the terminal process of the pigment epithelial cells contains no other visible structures, apart from small vesicles and occasional membranes, when the eye is dark-adapted and the retinal pigment withdrawn. Each sphere is surrounded by a thin membrane, visible as a fine dark line in electron micrographs when part or all of the lipid content of the sphere has been dissolved away. When the material was examined by the freeze-etch technique, the membrane could often be seen as a separate structure, cleaving differently from the internal component. The freeze-etch electron micrographs (Fig. 2) also provided confirmatory evidence of the shape, dimensions, and distribution of the tapetal spheres. The membrane is not a "unit membrane", but is similar to those associated with some plant lipid bodies[4-6], and in lymph chylomicrons[7]. The membranes surrounding the lipid spheres (bodies) in the corn root were termed "boundary membranes" by Trelease[6] who was able to observe them both *in situ* and after isolation. The tapetum has a fairly high refractive index, judged to be close to n_D^{23} 1.50, as determined by the immersion method using Thoulet's solution.

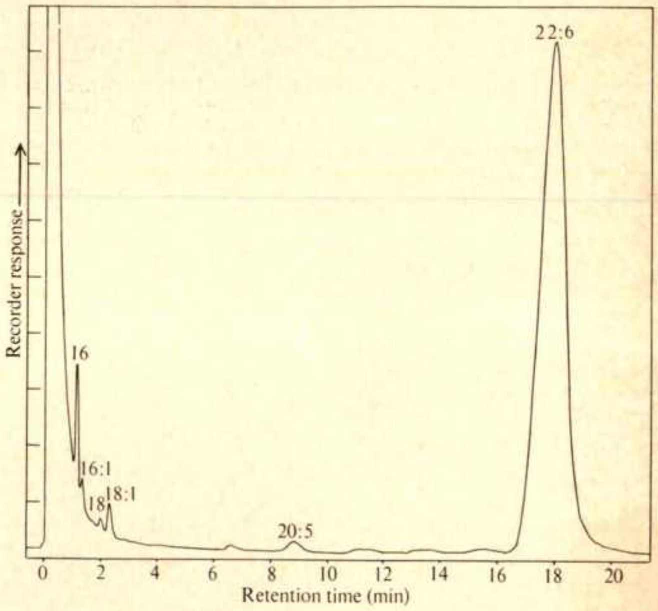

Fig. 3 Gas-liquid chromatograph of a transesterified sample of lipid from the tapetum lucidum of the sandtrout. Operating conditions were: Perkin-Elmer gas chromatograph, model 880; the analysis was carried out on a column of copper tubing, 6 feet × 1/8 inch, packed with 'DEGS' 10% on 'Gas-Chrom Z' (mesh size 60/80); carrier gas was helium, flow rate was 45 ml./min; the column was operated isothermally at 180° C.

To characterize the reflecting material, the pigment epithelium was removed from the eyes of dark-adapted fish; the material contained the entire pigment epithelial cell, including the white reflecting material, melanin, and other cellular organelles. It was cytolysed in distilled water and lightly centrifuged, and the supernatant contained the white reflecting material which was then extracted in chloroform and examined by thin-layer chromatography. It consisted almost exclusively of one major component running with triglycerides. Extracts of the entire pigment epithelium and whole retina contained the same principal component running with the triglycerides. Isolated retina did not contain a large triglyceride component. To secure larger amounts of material, therefore, whole retinas

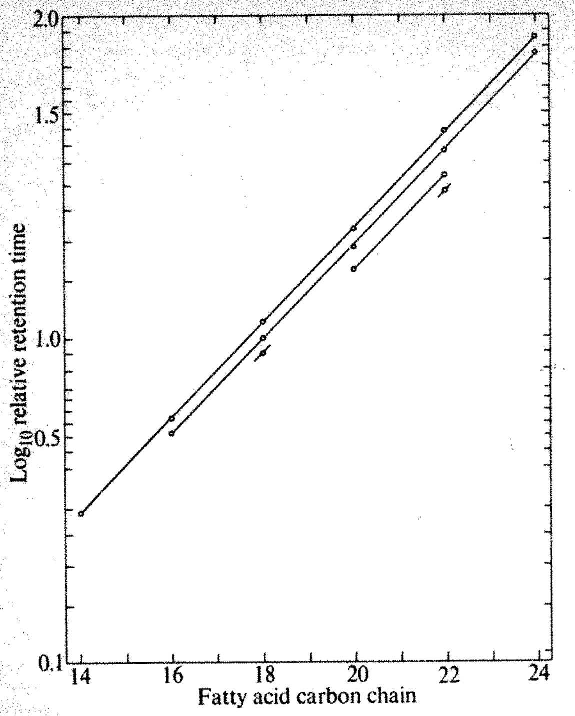

Fig. 4 Plot of $\log_{10}$ retention times against carbon number of fatty acid methyl esters and of the main component from the tapetum lucidum of the sandtrout. Retention times relative to methyl octadecaenoate. Lines from above downwards, saturates, monoenoic, dienoic (n-C18 : 2) only, pentaenoic, hexaenoic (authentic n-C22 : 6 and sample of tapetum). Data from a gas-liquid chromatograph record of a standard mix co-injected with a sample of unknown. Operating conditions: column of copper tubing, 5 feet × 1/8 inch packed with 10% 'Apiezon-L' on 'Gas-Chrom Z', carrier gas helium, flow rate 45 ml./min, isothermal run at 225° C.

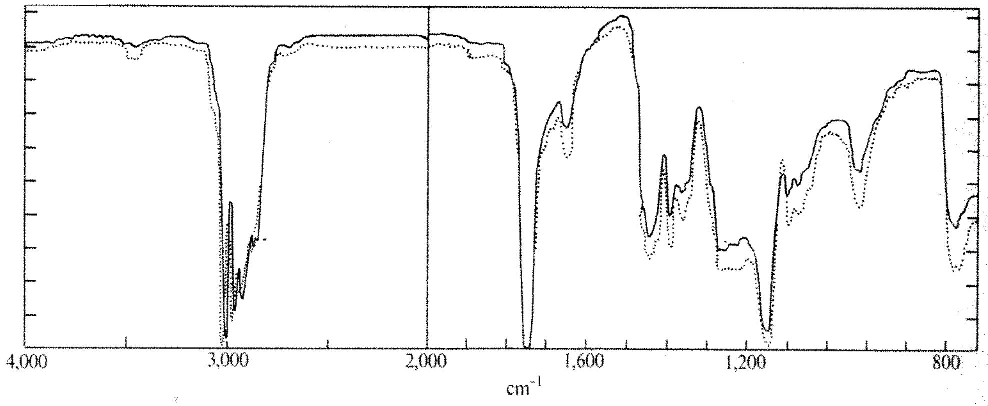

Fig. 5 IR spectra of lipid from the tapetum lucidum of the sandtrout (continuous line) and of authentic tridocosahexaenoin (Hormel Institute, estimated purity >90%, interrupted line). Spectra obtained on a Perkin-Elmer grating infrared spectrophotometer, model No. 237B. Solvent, carbon tetrachloride in sodium chloride cells. Fast scan.

including the pigment epithelium were collected (fifty eyes). They were extracted in chloroform–methanol by the method of Folch *et al.*[8], and the major component was isolated by column and preparative TL chromatography[9]. The eluant, examined by thin-layer chromatography in three different solvent systems, resembled triglycerides in chromatographic behaviour, and was well demarcated from phospholipids, sphingomyelin, cerebrosides, mono- and dipalmitins, cholesterol, cholesteryl esters, waxes, and diacyl glyceryl ethers. It was hydrolysed, esterified or transesterified and the presumptive methyl esters examined by gas-liquid chromatography on four different columns, ranging from non-polar to very polar (FFAP on 'Gas-Chrom Q', 'Apiezon-L' on 'Gas-Chrom Z', 'DEGS' on 'Gas-Chrom Z', and 'EGSS-X' on 'Gas-Chrom P'). The sample showed some minor peaks corresponding to various methyl esters of fatty acids from C14 to C22 : 5, and one major peak corresponding to n-C22 : 6 (Fig. 3). The latter comprised 95% or more of the fatty acids present. Confirmation was offered by a plot of log retention times against carbon number (Fig. 4). Further evidence for the chain length was provided by hydrogenation after which more than 95% of the fatty acid was converted to C22 : 0.

The evidence indicated that the reflecting material was a triglyceride containing docosahexaenoic acid. The original purified extract ran at the same rate on thin-layer chromatography as tridocosahexaenoin, and infrared spectra of sample and of authentic tridocosahexaenoin were closely similar (Fig. 5). It was concluded that the reflecting material consisted largely or almost exclusively of tridocosahexaenoin.

The occurrence of a simple unmixed triglyceride in a tissue is unusual; in depot fats of invertebrates and fishes, triglycerides are usually asymmetric, and n-C22 : 6 occurs preferentially in position 2 (proportionality constant $y_2 = 2.06\chi$, where χ = mol% 22 : 6 in the total triglycerides[10]).

The refractive index measurement of tridocosahexaenoin is not available, but that of fatty acid n-C22 : 6 is 1.49, and that of tridocosahexaenoin may be close to it.

The extract is transparent and very refractile; the diameter of the lipid spheres is about one wavelength (of visible light) and they act as Mie scatterers. Measurements and calculations (to be presented elsewhere) show that the tapetum is an efficient diffuse reflector. The system allows the fish to use light more efficiently in dim illumination, when rod vision or twilight vision is operative. Seatrouts along the coast of the Gulf of Mexico live in shallow waters containing a great deal of suspended material, and often encounter low levels of illumination during daylight hours. Light which passes through the photoreceptor layer of the retina without being absorbed is reflected back into the photoreceptor zone by the lipid spheres in the pigment epithelial cells. This second passage through the photoreceptors allows more light to be absorbed and seems to be effective in promoting vision in dim light conditions.

Mycorrhiza and Litter Decomposition

FORMATION of the mor type of forest litter, characterized by slow decomposition, has been attributed to a number of factors[1-3], but the effect of mycorrhizal fungi, though postulated[4,5], has not been studied experimentally. We have conducted an experiment in which root activity and thus mycorrhizal activity were reduced in small areas of an unthinned *Pinus radiata* stand. The following treatments (three replicates in a randomized block design) were applied to 1 × 1 m plots sited between the trees.

(*A*) The plot boundary was cut to a depth of 30 cm at commencement and recut every 2 weeks. All litter was removed to a sheet of hessian with minimum disturbance. As many roots as possible were removed from the soil to a depth of 30 cm and the litter was carefully replaced.

(*B*) The plot boundary was cut as above and the litter was removed. The soil was dug over to a depth of 30 cm but no roots were removed. The litter was replaced.

(*C*) The plot boundary was cut as above. The plot was not dug, nor were any roots removed. The litter was removed and replaced.

(*D*) The control plot was neither dug nor cut, but the litter was removed and replaced.

Table 1 Dry Weight of Litter from Sample Plots after 12 Months

Treatments			
A	*B*	*C*	*D*
474.8 ± 211.5	351.6 ± 133.7	659.0 ± 328.4	1,681.7 ± 213.9

The figures represent the means (in grams) of three replicates ± the standard deviation.

After 12 months the weight of litter per plot which had received treatment *D* was significantly ($P<0.001$) greater than in those given treatments *A*, *B* and *C*. Experimental design ruled out the effect of soil disturbance or decomposition of severed roots. It seems clear that the presence of living roots suppressed litter decomposition in some way. *Pinus* is a highly mycotrophic genus[6], and for practical purposes *P. radiata* roots in the field may be considered as mycorrhizas. The observed effect could be a result of some physiological activity of the tree roots functioning as a separate entity. On the other hand, it was observed that basidiomycetous mycelial wefts, normally very conspicuous in the litter, were completely absent from plots which had received treatments *A*, *B* and *C* although they were obvious in plots given treatment *D*. We suggest that these wefts were the external mycelium of the mycorrhizas. An alternative explanation for the litter weight results is that fungi of the mycorrhizal partnership, having a biological advantage because they are not dependent on litter for an energy source, become dominant in the litter and suppress the activity of saprophytic organisms. Litter decomposition slows down and conditions favouring mor formation result.

Immunological Suppression of the Occurrence of Spontaneous Mammary Tumours in C3H/He Mice

MICE immunized with syngeneic tumours acquire resistance to subsequent transplantation of mammary tumours[1-3], but there have been no reports of the immunological suppression of the spontaneous occurrence of the tumours by the use of appropriate specific antigens. Mouse mammary tumours appear in favourable conditions in a high percentage of both virgin and bleeding female C3H mice[4]. Mice of the C3H/He strain are genetically pure (syngeneic) and acquire the mammary tumour inducing virus (MTV) by vertical transmission.

We have assumed that the occurrence of spontaneous mammary tumours in C3H/He mice would be suppressed by immunization with the specific antigens of the mammary tumour.

The tumour specific transplantation antigen (TSTA) of mouse mammary tumours can be extracted from MM102 cells—the ascitic line derived from a spontaneous mammary tumour in a C3H/He mouse[5]. The TSTA extracted from MM-

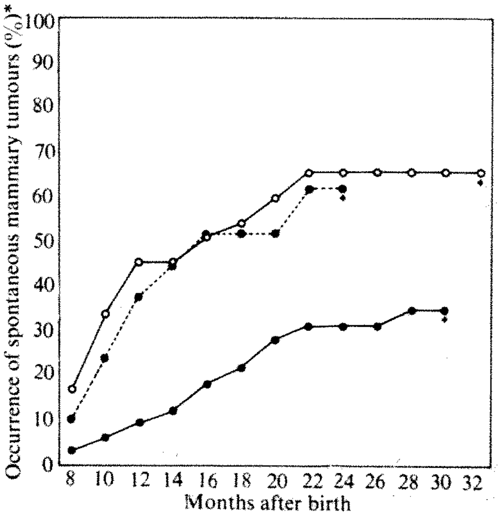

Fig. 1 Occurrence of spontaneous mammary tumours in C3H/He mice. Each plot is figured out the total occurrence within the months. —●—, Immunized with MM-antigen; - - - ● - - -, treated with C3Hf organ extract; —○—, untreated. +, All mice were dead by the marked month.

102 cells is termed MM-antigen. C3H/He mice immunized with MM-antigen acquire resistance to the transplantation of MM102 cells[5] and antibodies which specifically elicit immunological cytotoxicity on MM102 cells can be demonstrated in both the sera and the lymphatic cells of the resistant mice[6]. Further, two experiments suggest the existence of an antigen common to spontaneous mammary tumour cells and MM-antigen. Electron dense precipitates on the cell surface of the microvilli of spontaneous mammary tumour cells treated with RMS (syngeneic antiserum against MM-antigen) can be seen under the electron microscope, using the peroxidase labelled antibody method[7]; and immune cytotoxic activity of RMS can be demonstrated in primary tissue culture cells of mammary tumours[8]. It therefore seemed possible that spontaneous mammary tumours in C3H/He mice might be suppressed by immunization of these mice with MM-antigen.

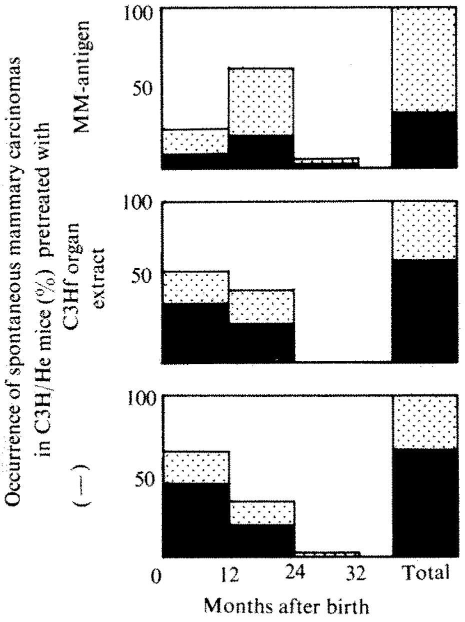

Fig. 2 Occurrence of spontaneous mammary tumours in C3H/He mice. The results are summarized at the end of each year. Shaded bar indicates the percentage of mice with spontaneous mammary tumours. Stippled bar indicates the percentage of dead mice not bearing the tumour.

We divided 105 C3H/He mice about 8 weeks old into three groups of thirty-five. Mice of the first group were immunized with MM-antigen. The visceral organs apart from the lymphatic organs of C3Hf mice were treated beforehand with the same method as extracting MM-antigen from MM102 cells (C3Hf mice are syngeneic with C3H/He mice but do not possess MTV). The second group of mice was immunized with this extract. The third group of mice was untreated. Immunization was carried out as follows. On the first, third and fifth days the mice of the first group were injected intraperitoneally with 0.5 ml. of 1 : 100 dilution of the MM-antigen (1 ml. of the undiluted antigen used here was extracted from 2×10^7 MM102 cells). On the seventh, ninth and eleventh days the mice were injected with 0.5 ml. of 1 : 50 dilution of the antigen. On the thirteenth, fifteenth and seventeenth days the mice were injected with 0.5 ml. of 1 : 25 dilution of the antigen, and on the nineteenth day the mice were injected with 0.5 ml. of 1 : 10 dilution of the same antigen. The mice were then boosted with 0.5 ml. of the undiluted MM-antigen once a month for 3 months. Immunization of the mice ended within 6 months after birth. The injection of extract from C3Hf organs into mice of the second group was carried out by the same method as that of MM-antigen into the mice of the first group.

In the sera of the mice in the first group the antibody reacted specifically with MM102 cells; this could be demonstrated by the immune adherence method until the thirteenth month after the end of immunization, although the antibody titre gradually decreased.

All mice were given dry feed and water *ad libitum* in the same conditions. Three mice from the first group and six mice from the second died during the immunization process, and were omitted from all calculations. The mice were examined for spontaneous mammary tumours once a week after the end of the immunization schedule.

The occurrence of the tumours in the first group was considerably suppressed compared with the second and the third groups (Fig. 1). No significant differences appeared between the second and the third groups. All the results (Fig. 2) were summarized at the end of each year for a period of 3 years. The suppression within the first year was quite drastic in the first group. There was no significant difference in deaths from other causes in the first year. The total occurrence of the tumours over 3 years in the first group was approximately one half of those in the second and third groups.

We thank Drs K. Nishioka and S. Takeuchi for helpful discussions and Miss K. Ueda for technical assistance.

Chromosome Polymorphism in American Negro and White Populations

THE biological and clinical implications of variations of human chromosome lengths are poorly understood.

In the study we now report, minor variations in chromosome length were correlated with clinical and sociological data obtained from each patient for 4,482 consecutively born infants. By far the strongest correlations were between certain minor chromosome variants and race. Most variants showing a racial difference of frequency were twice as common in Negroes as in Caucasians.

The human variants can be considered as polymorphisms as in *Drosophila* and other species[1-3] because (1) they occur at relatively high frequencies; (2) they are usually associated with normal phenotypes and (3) they are frequently inherited from generation to generation[4,5]. Racial variation of the length of the *Y* chromosome[6], and the question of racial variation in the size and morphology of the short arms of the chromosomes in groups *D* and *G*[7] have already been discussed.

All infants of more than 20 weeks gestation born at Yale–New Haven Hospital from October 1967 to October 1968 were included in the study and good preparations were obtained from the cord blood of 4,366 of 4,482 newborns[8,9]. Cells were treated with 0.075 M KCl and stained with orcein. Two karyotypes were examined from each infant and variation in length was scored using callipers. Variants were detected by comparing the lengths of individual chromosomes against internal standards within each cell (Table 1) and were recorded only when present in both cells. A long *Y* chromosome, for example, was recorded if the *Y* chromosome in both cells was greater than or equal to *F*19 in length, and an unusually long *Y* recorded if it was greater than the total length of *E*18 (Fig. 1). All the results are based on samples of two cells per individual. Studies with larger samples show that, in general, two-cell ascertainments are correct except for the commoner variants. The frequencies of $Y \geq 19$, short arm of *D* or *G* = *E*18 short arm, and both *E*16 variants were, however, overestimated, and the frequencies reported in Table 1 should not be used to estimate the actual frequencies of these variants.

Table 1 Frequencies of Polymorphisms in Caucasian and Negro Infants

Type of variation	Children of 3,476 Caucasian mothers *N*	%	Children of 807 Negro mothers *N*	%	*P*
Increased secondary constriction region *A*1	8	0.23	3	0.37	ns
Unusually metacentric *C* chromosome	2	0.06	10	1.24	<0.01
Short arm of a group *D* chromosome:					
Increased length (= *E*18 short arm)	480	13.80	171	21.18	<0.01
Increased length (> *E*18 short arm)	0	0.25	7	0.87	<0.01
Large satellites (> short arm same chromosome)	78	2.24	34	4.21	<0.01
Tandem satellite	3	0.09	2	0.25	nt
Streaked satellite	1	0.03	1	0.12	nt
Short arm absent	2	0.06	0	0	nt
Variations in long arm of *E*16:					
Increased length (> short arm *C*6)	71	2.04	32	3.96	<0.01
Decreased length (*E*16—*E*18)	19	0.55	3	0.37	ns
Short arm of a group *G* chromosome:					
Increased length (= *E*18 short arm)	81	2.33	45	5.58	<0.01
Increased length (> *E*18 short arm)	2	0.06	0	0	nt
Large satellites (> short arm same chromosome)	92	2.65	36	4.46	<0.01
Tandem satellite	3	0.09	0	0	nt
Streaked satellite	1	0.03	0	0	nt
Variations in length of the *Y* chromosome in 1,741 Caucasian and 411 Negro males:					
Y long (> F19)	253	14.53	60	14.59	ns
Y long (> E18)	6	0.34	1	0.24	ns
Y short (< G22)	7	0.40	2	0.48	ns
Y metacentric	2	0.11	0	0	nt
No polymorphism	2,131	61.31	389	48.20	<0.01

nt, Not tested because of small *N*. ns, χ^2 test for difference in frequency between Caucasian and Negro infants not significant (>0.05).

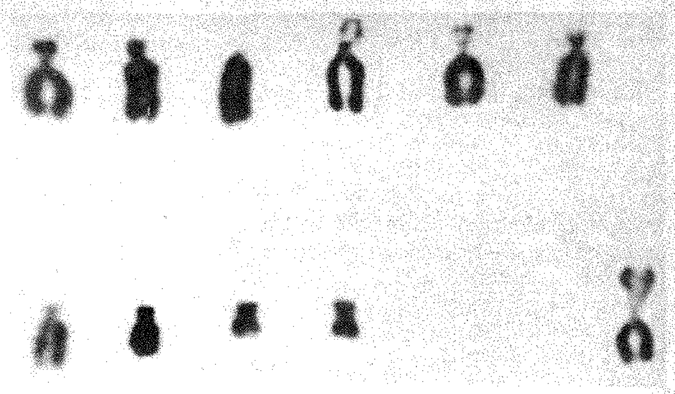

Fig. 1 Minor chromosome variants. In the top row, six polymorphisms in group *D* are shown (left to right): very long short arm ≥E18 short arm, long short arm = short arm *E*18, deleted short arm, long streaked satellites, large satellites (> short arm), and tandem satellites. *Y* chromosome polymorphisms in the bottom row are: *Y*> *E*18, *Y*> *F*19, *Y*< *G*22, *Y* metacentric. An example of a metacentric *C* chromosome with a secondary constriction adjacent to the centromere is shown at the far right, bottom row. Conventional staining with orcein.

The most marked difference between races occurred in the frequency of metacentric *C* chromosomes (Fig. 1). This chromosome was observed in only two of 3,176 Caucasian children but was a relatively common variant in Negro children occurring in ten of 807 children (1.2%, a twenty-fold difference). In every case the chromosome was characterized not only by an unusual degree of metacentricity but a secondary constriction adjacent to the centromere (Fig. 1). All the children were phenotypically normal except for one of the two Caucasian children who had a birth weight below 2,500 g. Precise identification of this chromosome is difficult with conventional staining, but in two cases restaining with quinacrine mustard[9] showed it to be chromosome *C*9. Of sixteen newborns with a short arm of a *D* chromosome greater than the short arm of *E*18, seven were Negro and nine Caucasian, a four-fold difference in frequency. The most common autosomal minor variants occurred twice as often in Negro children as in Caucasian children (Table 1). The common denominator in each of these seven variants was the presence of a secondary constriction in each of the involved chromosomes. Moreover, each of the acrocentric short arm variants is believed to share a common function of nucleolar organization and association, unlike the metacentric *C* and *E*16 variants, although secondary constrictions are present in both.

The relative differences in frequencies in the *D* and *G* group between Caucasian and Negroes were consistent with those found in the smaller sample of twenty Caucasian and twenty Negro children reported by Starkman and Shaw[7]. Similarly, the earlier work by Cohen and Shaw[6] did not show a difference between twenty Caucasian and twenty Negro adults, although a long *Y* chromosome occurred more commonly in twenty Japanese males. Data are presented in this study only in Caucasian and Negro infants because the number of other infants included in the study was small, but of nine unusually long *Y* chromosomes (*Y*> 18) one occurred in a Chinese baby and one in a child of Turkish parents. Only one Turkish child and nine male Chinese infants were included in the study. The clinical significance of these minor variants is also under study and in at least one case a statistically significant correlation has been established: the presence of a *Gp*(sat)+ variant in Caucasian infants was associated with a two-fold increase in the frequency of low birth weight[8]. Certain of the rare variants may also carry an increased risk in Caucasian infants[9]. Racial polymorphisms, however, seem to be the most common correlate of chromosomal variation.

The relative frequencies of the variants may represent an equilibrium between their rates of generation in and elimination from the two populations. The lower frequency of chromosome polymorphism in the Caucasian population may be related to with certain of the polymorphisms in Caucasians. The rate of elimination of the polymorphism from the Caucasian population would be more rapid, hence the equilibrium value would also be lower. Such an argument implies a similarity in the genetic effects for the numerous chromosomal variants observed, and it is difficult to imagine such a unifying factor. It is interesting, however, that most variants occur in heterochromatic regions of the chromosomes, either adjacent to centromere regions or in the distal part of the *Y*. These regions have been shown to contain redundant DNA which probably does not code for mRNA. Changes in the amount and/or distribution of heterochromatin may affect the expression of genes. The regulation of nucleolar organization regions, which occur in the short arm of the *D* and *G* chromosomes, may be particularly affected. It is also possible that the heterochromatin is basically different in the two populations or that differences in the genetic backgrounds respond to similar modifications of heterochromatin in different ways. More definite statements may be possible after examination of the variant chromosomes using newly developed techniques for the visualization of heterochromatin[11-14].

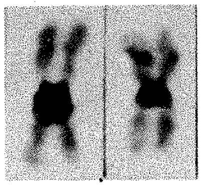

Fig. 2 Increased centromeric heterochromatin in chromosome *A*1. *A*1 homologous chromosomes from an individual heterozygous for increased long arm length. Ascertainment was first made by length measurement. Increased length in one *A*1 chromosome is correlated with increased heterochromatin. Polymorphism is heritable. Heterochromatin is visualized by first denaturing the chromosomal DNA *in situ*, then staining with Giemsa. Details of this method are presented elsewhere[12-14].

A family possessing an unusually long arm of chromosome *A*1 has been recently studied using these methods[12-14]. The results show that the extra length of the chromosome *A*1 long arm is caused by an increase (approximately × 2) of centromeric associated heterochromatin (Fig. 2) which provides preliminary support for the arguments presented here and suggests that other minor variants may be causally related to polymorphisms restricted to heterochromatic areas. Another finding in support of this viewpoint is the high frequency of length variation associated with the *A*1, *C*9, *E*16 and *Y* chromosomes. These chromosomes all contain very large blocks of heterochromatin[12-14]. We are re-examining our families possessing these polymorphisms. If variations in length generally prove to be due to variation in the length of heterochromatin areas, this would explain the benign effect of most such variants on phenotype and hence their high frequency. Lastly, because the polymorphic homologue can now be readily identified by a simple staining technique, it should be a simple matter to determine its pattern of inheritance in kindreds. This should provide extremely useful material for the purpose of establishing gene linkage to specific chromosomes.

Role for Ferredoxins in the Origin of Life and Biological Evolution

THE ferredoxins are members of a class of metalloproteins known as iron–sulphur proteins which act as electron carriers in such diverse biochemical processes as carbon metabolism, nitrogen fixation, photosynthesis and steroid hydroxylation[1,2]. They are relatively small proteins with molecular weights of 6,000 to 12,000; they contain 2–8 atoms of iron and equivalent amounts of inorganic sulphur per molecule, transferring electrons at low redox potentials (-300 to -500 mV at pH 7) and having a characteristic electron paramagnetic resonance signal at $g=1.94$ in the reduced state. Ferredoxins have been found in a wide range of organisms, from the primitive anaerobic bacteria to all higher plants and animals. A knowledge of the changes in their amino-acid sequence[3] is therefore of great value to the study of the evolution of these organisms.

We propose that a ferredoxin may have been among the earliest proteins formed and that ferredoxins may be very suitable for use in the study of the evolution from anaerobic to aerobic organisms. The ferredoxins from anaerobic bacteria have a very simple composition which seems to have developed into the more complex ferredoxins of the photosynthetic bacteria. The final stage of development was reached with the appearance of the primitive blue–green algae whose ferredoxin seems to be similar to those of all other algae and higher plants.

When life started, the principal mode of metabolism is thought to have been anaerobic fermentation of organic compounds which had formed abiogenically in the primaeval environment[4,5]. The ferredoxins probably played a significant role in the development of the fermentative bacteria. In present day organisms of this type such as the clostridia, the ferredoxins are simple, small proteins of fifty-five amino-acids and molecular weight 6,000 with a primitive polypeptide structure[6]. The amino-acid sequences of three of them are known[7-9]. These contain fourteen different types of amino-acids but only nine are common to all three ferredoxins. Significantly, the six amino-acids detected[11,12] in the Murchison meteorite (which fell in Australia in 1969)[10]—glycine, alanine, valine, proline, glutamic acid and aspartic acid—constitute 64% of the total amino-acid content of *C. butyricum*[8], while the nine "common" amino-acids (the six plus serine, cysteine and isoleucine) comprise 91% of the ferredoxin molecule of *C. butyricum*. All nine of these amino-acids have been synthesized abiogenically in conditions which simulated the primitive Earth environment in the laboratory[4]. The amino-acids methionine and histidine, which are difficult to synthesize in these laboratory conditions, are absent from these ferredoxins.

Unlike other electron-transferring proteins, such as cytochromes and flavoproteins, which have complex organic molecules in their active site, the ferredoxins have only iron and inorganic sulphur. Once the polypeptide chain of ferredoxin was formed, these could readily be added as an iron salt and sulphide, both of which were abundant in the primitive Earth. This process is known to occur readily in anaerobic conditions[13].

Fig. 1 Sequences of type 4 (plant) ferredoxins. The underlined amino-acids, of which there are sixty, are invariant. A, *Scenedesmus*; B, spinach; C, *Leucaena*; D, taro.

There seem to be four types of ferredoxins and they may be linked in the evolutionary pattern: (1) anaerobic fermentative bacteria ⟶ (2) green photosynthetic bacteria ⟶ (3) red photosynthetic bacteria ⟶ (4) algae and higher plants. The final stage in the development of ferredoxins seems to have occurred in the change from anaerobic photosynthetic bacteria to the aerobic photosynthetic organisms. The process of photosynthesis requires a donor of electrons which, with energy from the Sun, is used to reduce carbon dioxide to organic material. In the earlier photosynthetic bacteria the electron donor was probably H_2S or some other inorganic molecule; in algae and plants the donor was water and oxygen was evolved. This process is thought to have brought about the conversion of the primaeval reducing atmosphere into an aerobic one[14] so that animal life could develop. The first organisms to carry out this type of photosynthesis were probably the blue–green algae. These are prokaryotic, having no nuclear membrane or chloroplast outer membrane, but they differ from bacteria in that their photosynthetic apparatus is organized in a system of intracellular lamellae and they have type 4 ferredoxins. There is a big difference between these plant-type ferredoxins and the photosynthetic bacterial ferredoxins, and this probably reflects the large evolutionary change in photosynthesis that this step involves. The length of the polypeptide chain was increased, the additional protein moiety probably being necessary for the ferredoxin to interact effectively with the specialized photosynthetic lamellar systems. Thus so far no ferredoxin intermediate between types 3 and 4 has been found.

The type 4 plant ferredoxins have molecular weights of about 11,500; they contain two atoms of iron and sulphur, and transfer only one electron[15]. All the plant ferredoxins are very similar in optical absorption, optical rotatory dispersion and electron paramagnetic resonance (our unpublished observations). Thus it seems that with the appearance of the blue–green algae, the development of the ferredoxin molecule was complete.

In the evolution of green algae and higher plants from the blue–green algae, the oxygen-evolving photosynthetic system and the type 4 ferredoxins seem to have remained essentially unchanged. This observation supports the suggestion that plant and algal chloroplasts are the descendants of blue–green algae which lived symbiotically inside the early plant cells[16]. Thus all chloroplast ferredoxins would be derived from a common ancestor, namely blue–green algae.

The type 4 ferredoxins listed in Table 1 span the range from the blue–green algae to higher plants. Although these ferredoxins are very similar in overall structure, there are differences in the detailed amino-acid sequences which offer potential means of following evolutionary relationships within this very wide range of organisms. At present, however, too few sequences are known to permit any attempt to construct an evolutionary sequence. The amino-acid sequences of four type 4 ferredoxins are shown in Fig. 1. Although these sequences are very different from the bacterial ferredoxins, evolutionary relationships between types 1 and 4 have been demonstrated by Matsubara *et al.*[17]. Four of the cysteines are invariant (there is no cysteine at position 18 in *Equisetum* ferredoxin[18]) and they are thought to be structurally involved in the active site.

A proposed model[19] for the active site of type 4 ferredoxins is shown in Fig. 2. Whether a similar type of unit is applicable to the other types of ferredoxin is unknown but it may be possible to extend the model to the 2-electron transfer ferredoxins of types 1, 2 and 3 as has been suggested by Gibson *et al.*[20].

The occurrence of iron–sulphur proteins in animals has not been dealt with here because little is known about them at present. But because of the recent recognition of their ubiquitous occurrence and role in important reactions such as oxidative phosphorylation and hormone synthesis, they will undoubtedly be investigated intensively in the next few years. As an example, the hydroxylase iron–sulphur protein adrenodoxin from adrenal glands contains two iron atoms and two sulphur atoms and transfers one electron; its chromophore

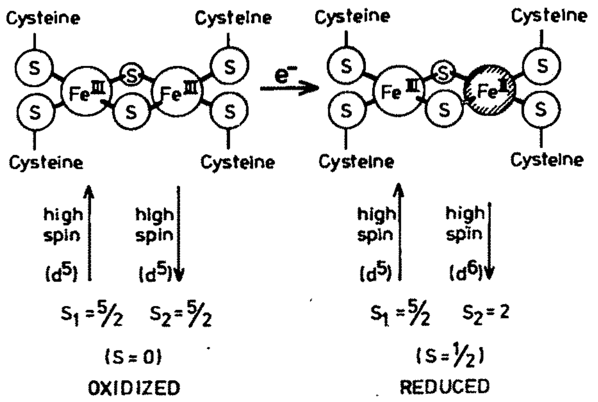

Fig. 2 Model of the iron–sulphur group in plant ferredoxins.

group seems very similar to the plant-type ferredoxins[21] but its amino-acid sequence[22] is quite dissimilar. Iron–sulphur proteins have also been detected in aerobic bacteria, fungi and yeasts[1].

Table 1 Amino-acid Composition of Type 4 (Plant) Ferredoxins

Amino-acid	1	2	3	4	5	6	7	8

In conclusion, ferredoxins may have been among the simplest proteins, being first formed as a short polypeptide chain of twenty-six amino-acids comprising only nine different amino-acids which are easily formed in simulated primaeval conditions. It might have been possible for the primitive organism to utilize the amino-acids from its environment to synthesize this simple protein. Inorganic iron and sulphur were available in abundance and could readily combine with the apoprotein in a non-enzymatic reaction to form the chromophore group of a ferredoxin which could transfer electrons at reducing potentials of −420 mV similar to those of H_2 gas. From studies of amino-acid sequence the ferredoxins seem to have evolved from the anaerobic fermentative bacteria to the anaerobic photosynthetic bacteria and thence to oxygen evolving, photosynthetic organisms. At some stage, proteins similar to the ferredoxins were incorporated into the metabolic pathways of animals, yeasts and fungi, also catalysing electron transfer reactions. Thus the ferredoxins are a class of proteins in which patterns of evolution can be followed.

Structure of α-Keratin

Low angle X-ray diffraction is a powerful means of investigating long range axial order in fibrous protein structures, and α-keratin was one of the earliest materials to be studied by this method[1]. The observed meridional and near-meridional reflexions have been indexed[2–5] as orders of an axial period of 198 Å, but there are indications[6,7] that this might not be correct. This possibility has been investigated using a high resolution focusing X-ray camera[8] to obtain diffraction patterns from several native keratins and from certain heavy-atom derivatives of porcupine quill.

It is difficult to calibrate fibre patterns with sufficient precision to combine results from different specimens and for the purpose of comparison it was assumed that the well resolved meridional reflexion about 24.8 Å corresponded to the eighth order of a 198 Å axial period. Thus the reciprocal space coordinate ζ of this reflexion was taken as 0.0404 Å^{-1} in each case and the indices of the remaining reflexions calculated on this basis. The results (Table 1) show that the measurements on keratins from different sources and on different derivatives agree in general to within the estimated experimental error of $\pm 0.2 \times 10^{-3}$ Å^{-1}. The ζ-values calculated on the basis of a 198 Å axial period are also listed and it will be seen that there are discrepancies considerably in excess of experimental error between the observed and calculated values. It seems therefore that the axial period of α-keratin is not 198 Å, as is generally supposed.

From a consideration of the results given in Table 1 an alternative axial period of 470 Å was derived and it will be seen (Table 1) that this enables all the observed meridional reflexions to be indexed in a satisfactory manner. In no case does the difference between the observed ζ-value and that calculated on the basis of a 470 Å axial period exceed the estimated experimental error. Further measurements on non-meridional low angle reflexions and on near-meridional high angle reflexions indicate that an axial period of 470 Å is likely to provide a satisfactory basis for indexing the complete diffraction pattern. For comparison, the diffraction patterns of the materials listed in Table 1 were placed on a common scale but the absolute value of the axial period is known to increase with hydration[2]. Measurements on dry porcupine quill dusted with a powdered calibrating substance give an absolute value of 470 ± 3 Å for the axial period in this material.

At low angles the prominent meridional reflexions fall on layer lines with indices (based on a 470 Å period) which satisfy the selection rule $l = 19\,m$, $19\,m \pm 5$ and $19\,m \pm 7$, where $m = 0$, 1 and 2. This type of distribution is characteristic of a periodically distorted structure[9,10]. A likely cause of such a distortion is that the fibrous elements (microfibrils) have an initial screw axis with 19 units in t turns of pitch $470/t$ Å which is disturbed when close packing of the microfibrils takes place during biogenesis. Strong near-meridional diffraction occurs on $l = 17$ and the lateral coordinate of the maximum is such that it could only be due to a first order Bessel function. From the Bessel function selection rule for a helical structure with u units in t turns ($l = um + tn$; where m and n are integers)[11] it follows that with $l = 17$ and $u = 19$, $t = 2$ for $n = -1$. This helix is illustrated in Fig. 1.

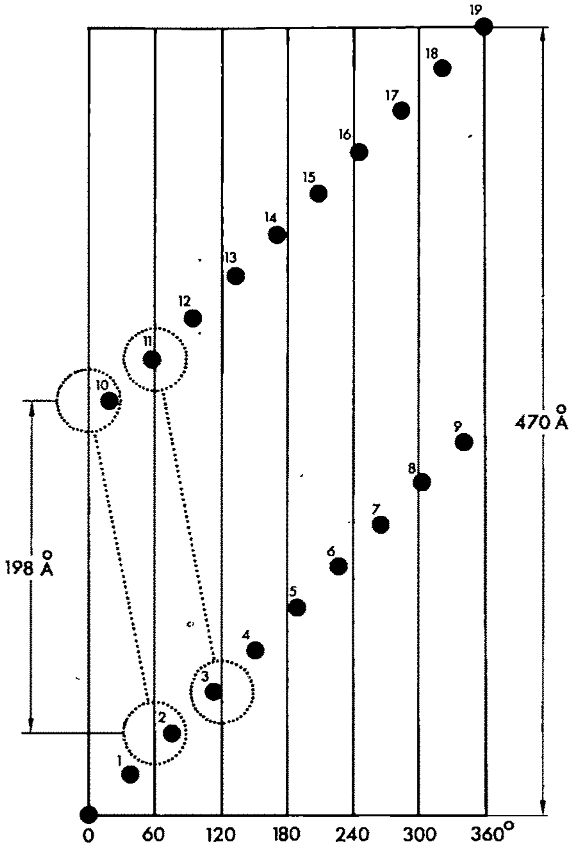

Fig. 1 Radial projection of the axial repeat of structure in the α-keratin microfibril. An isolated microfibril contains 19 units in 2 turns of a helix of pitch 235 Å giving an axial repeat of 470 Å. The vertical lines represent lines of contact with neighbouring microfibrils in a hexagonally close packed structure. Units separated by an axial translation of 198 Å (dotted lines) have almost identical environments and presumably similar distortions. The screw-sense of the helix cannot be determined directly from the X-ray data, but considerations of the way in which left handed coiled coil ropes could be packed side by side with a displacement of 24.8 Å suggest that better packing would be obtained with a right handed screw axis for the microfibril.

The origin of the 198 Å pseudo-period in the axial projection of the structure is immediately apparent from Fig. 1 where the contacts between a microfibril and its six nearest neighbours are indicated by vertical lines. Units separated by an axial translation of 198 Å have almost identical environments and

presumably therefore undergo similar distortions. The pseudo-period of 198 Å is thus a consequence of the pattern of distortion rather than an indication of molecular dimensions. The redistribution of intensity which occurs at low angles when α-keratin is hydrated[7] therefore reflects a change in the nature of the distortion pattern at the surface of the microfibril.

Our conclusions have several implications for further studies of the structure of α-keratin. (*a*) The microfibril has a nineteen-fold rotation axis in projection and a radius ~36 Å[12], and so it is unlikely that the individual structural units could be resolved when viewed in axial projection in the electron microscope[13,14]. (*b*) The interactions along the lines of contact between microfibrils are quite precise, suggesting that bridges exist between them or that the intervening matrix has, at least in part, a regular structure. (*c*) The microfibril in α-keratin is believed to be composed of molecules of molecular weight ~45,000 (ref. 15). If the number of such molecules associated with each unit in Fig. 1 were 1, 2 or 3 the corresponding microfibril radii would be, respectively, ~27, 38 or 47 Å assuming a density of 1.3 g cm^{-3}. The value derived for two molecules per unit gives the best agreement with the estimate of 36 Å for the radius of the microfibril in African porcupine quill derived from the low angle equatorial X-ray pattern[12]. A consideration of the distribution of intensity in the meridional pattern in various heavy atom derivatives, which will be discussed in detail elsewhere, suggests that the two molecules may be related by a horizontal dyad. (*d*) The prominent 5.16 Å arc in the high angle diffraction pattern does not index satisfactorily on a 198 Å axial period[16,17] but seems to fall on the ninety-first layer line of the 470 Å period. Weaker arcs at 5.06 and 4.96 Å fall on the ninety-third and ninety-fifth layer lines respectively. The diffraction in this area originates from the coiled coil ropes in the interior of the microfibril[12] rather than from the surface and the screw axis is less likely to be disturbed by inter-microfibrillar interactions. The appearance of low order Bessel functions on $l=91$, 93 and 95 is to be expected from the selection rule $l=19\ m+2\ n$ for a helix with 19 units in 2 turns.

Geometry of the Myosin Dimer

MONOMERIC myosin in aqueous solutions of high ionic strength is in rapid reversible equilibrium with a dimer species[1-3]. Because this dimer is likely to be the initiating and possibly the building unit in the formation of the thick filament of muscle, its three dimensional geometry is of considerable importance.

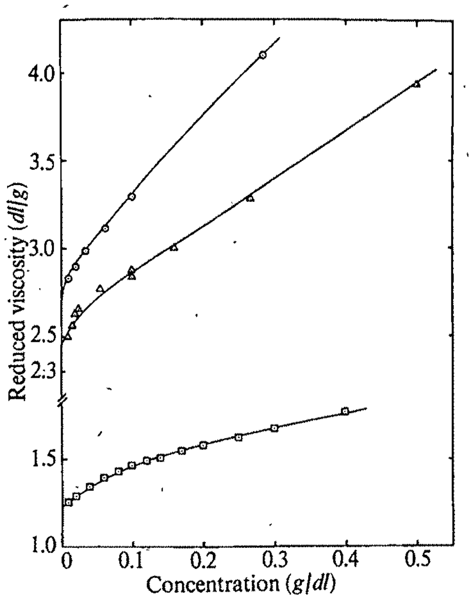

Fig. 1 The reduced viscosity as a function of concentration for myosin (△), LMM (□) and rod (○) at 5.0° C. A 10 min tryptic digestion of myosin was used to isolate LMM, while insoluble cellulose-papain was used for limited digestion of myosin to yield rod[13,14]. Both fragments were purified from low molecular weight components by fractionation on a column of 'Sephadex G-200'. All protein solutions were made up gravimetrically using solvents which had been passed through 'Millipore' filters. An Ostwald-type viscometer was used with an average shear gradient 300 s^{-1}. The outflow time for the solvent at 5.0° C was 146 s and the kinetic energy correction was found to be negligible. The solid curves represent the best computed fit to the experimental data (see text) with the corresponding parameters given in Table 1.

The solubility properties of light meromyosin (LMM) and "headless" myosin (rod), as well as X-ray[4] and electron microscopic evidence[5-8], suggest that the interaction sites responsible for the association of myosin reside primarily along the surface of its rod segment. Since the tendency for self-association of the myosin molecule is not completely repressed in high ionic strength media[2], both LMM and rod may also exist under these conditions in a rapid, reversible monomer⇌dimer equilibrium. This equilibrium may have been overlooked since both fragments, like myosin, exhibit single peaks in sedimentation velocity experiments, thus satisfying the criteria for either an apparently monodisperse non-interacting system or a rapid, reversible monomer⇌dimer equilibrium[9,10]. In the case of myosin, the presence of a rapid, reversible monomer ⇌dimer association[1] was established only after careful sedimentation equilibrium study and computer analysis[2,11,12].

We have found that both LMM and rod self-associate in high ionic strength media by a rapid, reversible equilibrium of the monomer⇌dimer type exhibited by myosin. This suggests that measurements of the asymmetry of these particles in dimerizing conditions could resolve the problem of whether the myosin dimer is formed through parallel or antiparallel association. The myosin molecule can be represented as a rod with a ball at one end. If two such structures are placed side by side in either parallel (head to head) or antiparallel (head to tail) arrangement and one of the two molecules is displaced axially with respect to its neighbour, for each displacement there are, for both LMM and rod, unique dimer structures which characterize the geometry of the parent myosin dimer. We have investigated the concentration dependence of the viscosity of LMM and rod in the ionic medium in which myosin is in a rapidly reversible monomer⇌dimer equilibrium.

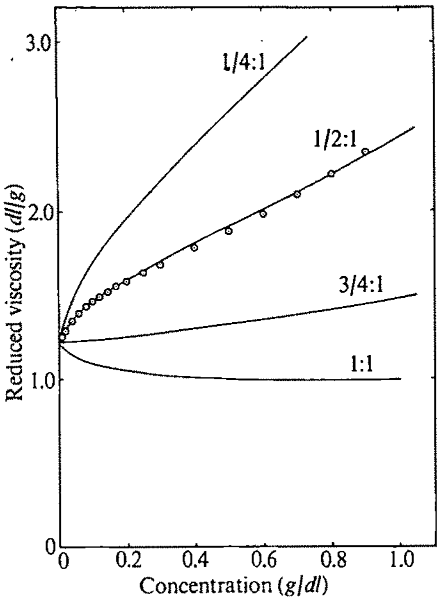

Fig. 2 The viscosity versus concentration dependence of light meromyosin (○) at 5.0° C. The solid curves represent the theoretical reduced viscosity versus concentration plots for LMM in a monomer ⇌ dimer equilibrium with respect to the specified dimer geometry. The parameters used to construct the theoretical plots are given in Tables 1 and 2. A value of 0.45 was assigned to the Huggins constant k'.

Plots of viscosity versus concentration of LMM, rod and myosin in 0.5 M KCl, 0.2 M PO_4 and 0.01 M EDTA, *p*H 7.3 (Fig. 1), all curve downwards at low concentrations in the manner expected for an associating system in which the associated species is more asymmetric than the monomer. In earlier studies[13,14], downward curvature was not detected since measurements were generally made at concentrations greater than 0.5 mg/ml. Moreover, there was no reason to assume that a monomer⇌dimer association reaction was occurring in these early studies. The downward curvatures of Fig. 1 cannot be due to binding of the protein to the capillary wall, since plots of the difference in outflow time between solution and solvent ($t-t_o$) versus protein concentration for these three particles extrapolated through zero at $c=0$[15]. The theoretical reduced viscosity versus concentration plots expected for a monomer⇌dimer equilibrium as a function of dimer geometry were calculated for light meromyosin (Fig. 2) by using the parameters given in Tables 1 and 2. The intrinsic viscosities of the dimer were evaluated from hydrodynamic studies of macromodels as described later. Assuming that a monomer⇌dimer equilibrium does exist and that the specific viscosity (η_{sp}) of the mixture will be an additive function of the specific viscosities of each of the species present, the specific viscosity of the equilibrium system can be expressed by the equation

$$\eta_{sp_{mixture}} = \sum_{i=1}^{2} \eta_{sp_i}$$

where

$$\eta_{sp_i} = \Big[[\eta_i] + k'\,[\eta_i]^2\,c_i\Big]\,c_i$$

c_i is the concentration of the i^{th} species. (*dl*/*g*) and k' is the dimensionless Huggins constant which, for non-associating systems, has values between 0.4 and 0.5.

The experimental data in Fig. 1 have been fitted using various values of K (the equilibrium constant) and $[\eta]_d$ with k' equal to 0.45. The intrinsic viscosity of monomer, $[\eta]_m$, was obtained by extrapolation of the experimentally obtained reduced viscosities to infinite dilution. The derived values of $[\eta]_d$ and K which best fit the experimental points are given in Table 1 and the curves generated from them are shown in Fig. 1. In the case of myosin the value of 10 *dl*/*g* was assigned to the equilibrium constant, this being the value found by high speed equilibrium sedimentation[2].

Table 1 Hydrodynamic Parameters derived from Reduced Viscosity versus Concentration Dependence of Myosin and its Proteolytic Fragments LMM and Rod

Particle	K(*dl*/*g*)	Theoretical (model studies) $[\eta]_m$(*dl*/*g*)	Experimental $[\eta]_m$(*dl*/*g*)	$[\eta]_d$ (*dl*/*g*)
LMM	5.52	0.910	1.23	1.90
Rod	27.5	1.73	2.65	3.42
Myosin	10.0(2)	—	2.45	3.11

To find the geometry of the dimer structure which would be consistent with the derived $[\eta]_d$ values of the three particles, we investigated the hydrodynamic behaviour of macromodels of differing dimer geometry[15-18]. The scaled up models were constructed from precision ground stainless steel rods of 0.317 cm diameter or from brass rods of 0.236 cm diameter. It was assumed that the LMM particle was 860 Å long and 20 Å in diameter and that the rod was 1290 Å long and 20 Å in diameter. Very close agreement was found between the experimental torque and that predicted by the Broersma expression for single rods of varying axial ratio[18].

The axial ratio of an effective ellipsoid having the same volume as the dimer was calculated from measurements of the torque required to rotate the specific dimer model with unit angular velocity in a solution of invert sugar of viscosity 200 poises at 22° C. The intrinsic viscosities expected for the various dimer geometries were derived from the axial ratio utilizing the Perrin[19] and Simha[20] equations and assuming apparent specific volumes of 0.710 and 0.728 for LMM (rod) and myosin, respectively[1]. The intrinsic viscosities expected for the monomeric LMM and rod particles, based on modelling studies, were smaller than those observed experimentally (Table 1). This discrepancy probably arose from the assumption of an incorrect geometry of the monomer used in the construction of our models. We have normalized the viscosities obtained from the model studies to take into account the geometry differences (Table 2).

Table 2 Intrinsic Viscosities derived from Hydrodynamic Studies of Macromodels of Differing Dimer Geometry

LMM			Rod		
Fraction of overlap	$[\eta]_d$(*dl*/*g*)	Dimer length (Å)	Fraction of overlap	$[\eta]_d$(*dl*/*g*)	Dimer length (Å)
1.0	0.613	~860	1.0	1.52	1290
0.75	1.23	1080	0.75	2.65	1610
0.50	1.82	1290	0.66	3.10	1720
0.25	2.74	1500	0.33	5.41	2150

In the case of LMM, the $[\eta]_d$ derived from the experimental curve is best fitted by a dimer geometry corresponding approximately to a 430 Å overlap. Similarly, in the case of the rod, the best dimer geometry corresponds approximately to a 780 Å overlap. Although various geometries for the myosin dimer would be consistent with the experimentally deduced dimer viscosities of LMM and rod taken separately, only one structure is consistent with the combined results from both particles. This structure is a parallel myosin dimer in which the head of one myosin molecule is displaced 430–510 Å with respect to that of its neighbour. The intrinsic viscosities of myosin should be somewhat lower than those of the corresponding rod structures because of the presence of the globular head. The value of $[\eta]_d$ for myosin (Table 1) is therefore consistent with the parallel-type geometry.

These results do not preclude the possibility that other dimeric structures exist, but in the conditions of these experiments the most likely structure is the dimer described. Moreover, Herbert and Carlson have shown, from their light scattering results, that the z-average radius of gyration of myosin has a concentration dependence that strongly supports the view that this parallel dimer is formed on self-association (unpublished results).

The geometry of the myosin dimer deduced here has interesting implications in the assembly of the thick filament of muscle. It is clear from the model of the thick filament proposed by Pepe[6] that the structure can be constructed in all its features entirely from this specific parallel-type dimer in which the head of one molecule is displaced about 430 Å with respect to its neighbour. The bare central region of the filament would be constructed by antiparallel (tail to tail) association of the dimer units. The filament would grow by head to tail addition of the dimers. Moreover, such a dimer has been invoked by one of us as the basic transducing element of skeletal muscle[21]. This proposal requires that the head of one molecule is in juxtaposition with the hinge section (trypsin sensitive region) of its neighbour.

We thank Dr T. J. Herbert and Dr F. D. Carlson for allowing us to quote from their findings before publication. We also thank Dr J. S. Barton and Miss T. Karr for assistance with the computer program and Miss S. Himmelfarb for technical assistance. This research was supported by the National Institute of Arthritis and Metabolic Diseases.

Extended Sleep and Performance

MOST studies of the psychological consequences of sleep have been concerned with the way in which sleep deprivation decreases performance[1,2]. Little has been done to discover the relationship between extended sleep and performance. It may therefore be of interest to describe a study in which unnaturally extended sleep has been found to be followed by decreased performance in certain tasks.

Twelve normal male college students, who regularly slept 7–8 h nightly, were requested to abstain from drugs including alcohol for at least 5 days before their first night in the experiment and until after the last. They typically averaged 7–8 h of sleep per night according to their sleep logs. On the days of the experiment latency from the last meal was controlled and subjects were instructed not to nap or to drink caffeinated beverages after 1800 h and to maintain their usual level of physical activity. Subjects were informed that the purpose of the experiment was to investigate the relation between sleep and personality.

An adaptation night preceded 2 control nights of habitual sleep and 2 nights of extended sleep with a 1 day recovery period between the last two conditions. Subjects slept in pairs and were always awakened at 0900 h following both conditions, but were not told this, and were served 6 ounces of fruit juice as a partial nutritional control for blood sugar level. In the extended sleep condition subjects retired at 2200 h and in the control condition they were in bed by 2200 h engaged in quiet activities until 0100 h when they were requested to sleep.

Calculation and vigilance tasks similar to those used by Wilkinson *et al.*[3] and a complex motor performance (pinball, Gottlieb "swing along") task were administered as performance measures at a fixed time to control for circadian effects. Order of presentation for the pinball and vigilance tasks as well as conditions of sleep were counterbalanced across subjects. The 50 min calculation task which involved adding 100 columns of five two-digit numbers was given 30 min after awakening. The number of sums added incorrectly and the time required to complete it was scored. Following the calculation task a 45 min pinball task and a 45 min version of the Wilkinson vigilance task[2] were administered simultaneously and alternately to each of the pair of subjects. For the vigilance task the measure of performance taken was the combined number of signals missed (omissions) and incorrectly detected (false reports). For the pinball task average score per game was scored, efficient performance being represented by a high score. Electroencephalographic, electromyographic and electro-oculographic activity was recorded and the records scored according to standard procedures[4].

Table 1 shows the number of minutes spent in each sleep stage, total sleep and wakefulness time and total time spent in bed during both nights of each sleep condition. Because of technical difficulties, the adaptation night was substituted for one of the control nights in computing the various means in Table 1. On nights of extended sleep, the mean time allowed for sleep was 10.6 h and, of this, subjects slept 9.1 h on average, with a range of 7.5–10.7 h. Most of the time spent in bed awake on these nights was generally attributable to long sleep latencies which averaged 47 min, a smaller portion of this period being due to terminal wakefulness, which averaged 21 min. On control nights the mean time allowed for sleep was 7.6 h and, of this, subjects slept 7.1 h on average with a range of 6.2–7.8 h. Wakefulness on these nights was minimal for most subjects. Comparisons between the two conditions for the amount of time spent in each sleep stage were reported previously[5].

Decrements in performance with extended sleep were significant for two measures: combined number of omissions and false reports on the vigilance task (Table 2; $P<0.005$, one-tailed Wilcoxon test) and average score per game on the pinball task (Table 2; $P<0.025$, one-tailed Wilcoxon test). There were no significant differences in performance between the control and extended sleep condition on the calculation task for either errors or speed of calculation (control condition: mean errors = 5.7, s.d. 3.53, mean speed = 25.4 min, s.d. 6.4; extended sleep condition: mean errors = 6.3, s.d. 2.03, mean speed = 24.2 min, s.d. 3.5).

It seems unlikely that the effect of prolonged sleep was due to variations in nutritional intake or less activity consequent to

a prolonged period in bed, for there were controls for these factors, but it is possible that the effect is related to sleep onset occurring at an earlier phase of the circadian rhythm. Because wakefulness tended to increase in the extended sleep condition, this might account for the decrements in performance. This increase, however, was primarily in sleep latency at the beginning of the night. Increased wakefulness during sleep increased at a rate of only 0.2 min/h. The increase in terminal wakefulness of 8 min does not seem to be a crucial factor, especially because testing on pinball and vigilance tasks did not begin until 75 min after subjects rose from bed. As in sleep deprivation experiments[6] and a previous study on extended sleep[2], accuracy on the subject-paced calculation task was insensitive to changes in amount of sleep, whereas the experimenter-paced pinball and vigilance tasks proved to be sensitive measures of impaired performance following manipulation of sleep variables.

Table 2 Average Performance on the Vigilance and Pinball Tasks after Two Nights of the Control (C) and Extended Sleep (E) Conditions

Subject	Combined errors of commission and omission on the vigilance task		Average score per game on the pinball task	
	C	E	C	E
1	7.5	8	592	643.5
2	9	8.5	557.5	583.5
3	14	15	464	516.5

12	20.5	41	548	490.5
S.D.	6.8	12	51.2	63.7
Means	10.6	16	563.5	514

It is well known that sleep deprivation impairs waking behaviour[7]. This investigation indicates that deviating from a habitual regime of sleep by extending sleep is detrimental to subsequent waking behaviour as well. We suggest that any general theory of sleep should attempt to explain both phenomena.

This study was supported in part by the US Public Health Service, Environmental Control Administration. We thank Drs Ralph Berger, Barry McLaughlin and Emanuel Lask for advice and assistance.

Single Cell Protein and the Exploitation of Mutant Algae lacking Cell Walls

MICROBIAL cells are potentially attractive sources of protein food, but this usefulness is at present limited, not merely by technical and economic difficulties[1–4], but also because the indigestibility of the cell walls limits the extent to which they

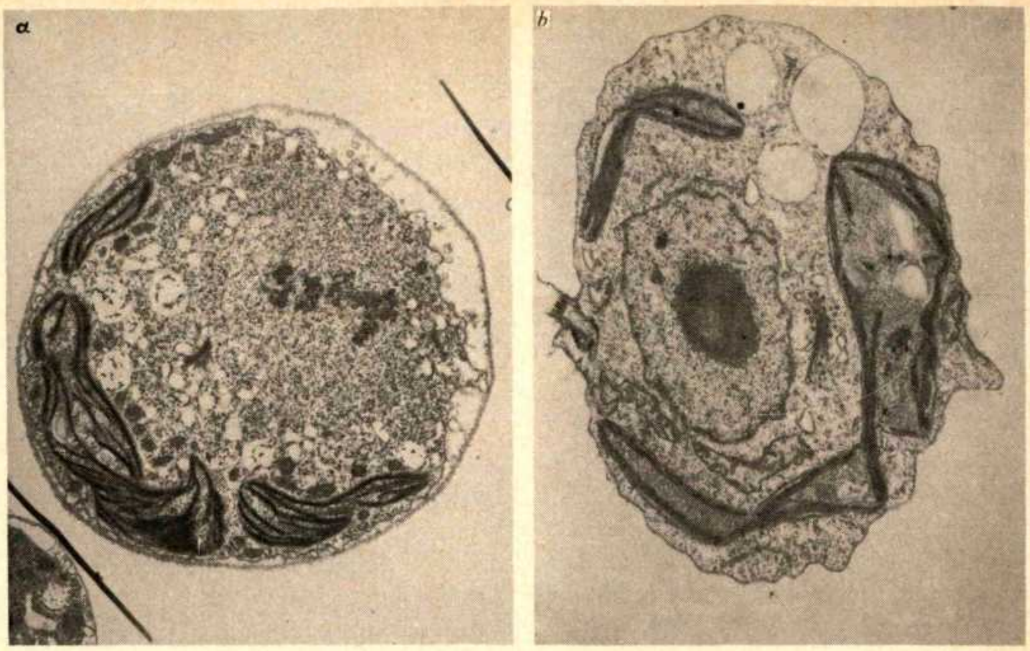

Fig. 1 Longitudinal section of (*a*) a wild type cell, (*b*) a mutant CW15, lacking a cell wall. Note cell is bound only by a plasma membrane. (Electron micrograph ×7,200.)

can be incorporated directly into human food. Indeed it has been suggested that microbial cells[5] and the alga *Chlorella*[6] cannot be used in human food without removal of the cell walls. For algae, there are two ways of overcoming this difficulty—either the material can be fed to ruminants, or mechanical, chemical or enzymatic techniques[7] can be used for the fractionation and removal of the cell walls. Enzymatic methods are as yet inefficient and, whereas industrial scale production in Czechoslovakia involves mechanical disruption of the algal cells with Ballotini beads, Japanese commercial production involves chemical extraction. Although all these methods are easy and efficient on a laboratory scale, on an industrial scale problems of fractionation are as formidable as those of cultivation[2]. Furthermore, the cost involved militates against a more general utilization of this food source. There is now evidence that by genetic manipulation it is possible in some instances to overcome these problems posed by the presence of the cell wall.

Table 1 Amino-acid Composition of Wild Type Cells and of a Mutant Strain CW15 Lacking Cell Walls

Amino-acid	mg in WT	mg in CW15
Lysine	0.78	0.85
Histidine	0.21	0.29
Arginine	0.81	0.86
Aspartic acid	1.11	1.21
Threonine	0.60	0.64
Serine	0.54	0.53
Glutamic acid	1.30	1.27
Proline	0.60	0.57
Glycine	0.68	0.64
Alanine	0.92	0.90
Half cystine	0.09	0.07
Valine	0.76	0.73
Methionine	0.35	0.49
Isoleucine	0.61	0.48
Leucine	1.08	1.08
Tyrosine	0.50	0.55
Phenylalanine	0.67	0.63
Total protein	11.61 mg	11.79 mg

20 mg of acetone–ether washed cells was used in each instance.

Following treatment with the chemical mutagen N-methyl-N′-nitro-N-nitrosoguanidine we have isolated in the unicellular green alga *Chlamydomonas reinhardi* a large number of mutants with various defects in cell wall biogenesis (ref. 8 and unpublished work). These are readily distinguished from wild type cells by their altered colony morphology. A few of these mutants produce no detectable quantities of cell wall (Fig. 1); in spite of this, some can show comparable growth rates to the wild type and in all respects they seem to be perfectly viable and normal when grown in liquid culture. Furthermore the cells retain ample mechanical strength to allow aeration, stirring, and harvesting by centrifugal separation. Since the nature and quantity of protein are of primary relevance in the context of single cell protein production comparative assays of protein content and of amino-acid composition of one of the mutant strains and of the wild type were undertaken. The results are given in Table 1. The percentage of protein in the wall-less mutant is comparable with that in the wild type although the wall itself does contain protein. The total weight of the wall, however, is small in comparison with that of the whole cell. The differences in amino-acid composition between the two strains are of little significance.

The potential value of such mutant forms of green algae lacking cell walls is immediately apparent in that it overcomes one of the most serious problems facing those who have sought to exploit them as a source of single cell protein[9]. While the particular mutants of *C. reinhardi* may have no significance as sources of single cell protein there is clearly every incentive for undertaking programmes to induce and isolate comparable mutant strains, not only of the algae now being grown on a commercial scale[4] but also of other microorganisms.

I thank Mr M. Rees for amino-acid analyses, and Miss K. Plaskitt for electron micrography.

BOOK REVIEWS

Success Stories

Contemporary British Chemists. By W. A. Campbell and N. N. Greenwood. Pp. 286. (Taylor and Francis: London, June 1971.) £5.

In a technological, numerate, post-Dainton society there is great advantage in producing graduates with some understanding of a physical science such as chemistry, without expecting them to rely on it too heavily in their post-university careers. To ignore details of the second law of thermodynamics matters little, provided there is some notion of the thought processes used in deriving it. Chemistry has become a core subject or, according to one eminent chemist in industry, has ceased to exist.

This point of view represents a revolution against the consensus of the past. Until the late fifties of this century, professors of chemistry walked ten feet high. The aspiring young chemist, thankful for intelligence and luck which allowed him to be accepted for and surviving an honours course, emerged at the end bursting with facts, more or less well digested, but certain that society will reward him appropriately for the years spent in dark satanic labs. These beautiful simplicities eroded under the twin pressures of facts and industrial forces. As the number of facts multiplied, it became simply impossible to digest more than a fraction in the three to four years available. A substantial portion of industry began its clamour for more and more of new style scientists, whose education would render them more suitable for managerial positions.

The response of chemical educators has been the notion of chemistry not as a vocational but as an educational discipline. Improvements in teaching methods both at school and at university resulted in enormously improved curricula and methodologies, and the new views have obtained if not universal at least widespread approval. Yet a paradoxical situation remains. To make science as attractive as possible to schoolchildren and undergraduates, their enthusiasm has to be aroused, but not to such a pitch that they should elect, in the vast majority of cases, to carry on with science after graduation. For the individual, education in science represents no longer a vocation for the discipline, but rather one for worldly success. Irrespective of any other consideration, the functional success of such an argument requires that for those who study chemistry, or the sciences generally, the resulting qualification should open all doors from Whitehall to Throgmorton Street and offer a level of comfort the young aspirant would like to be accustomed to.

The main argument of this book is that it is indeed possible to scale professional heights with a chemistry degree, even in fields that have little to do with chemistry itself. Its method is to present scientific and personal biographies of 145 successful people—all but five of them men—based on 180 questionnaires sent out by the authors. While the aim is excellent and the presentation of the book first class, the very complexities of changing society have introduced a number of difficulties. The selection of top people, not even within a profession but based loosely on it, is always a hazardous procedure: since under our system it is extremely unlikely for anybody to become obviously eminent very early in life, the success stories are products of the very educational ideas that have lost ground. Thus the vast majority of the 145 are professors of chemistry: undeniably important figures in the scientific landscape but hardly calculated to convey the message of a wide variety of career choices. The successful chemist appears to be doing what chemists have always been doing: research. *Se monumentum requiris, circumspice.* Yet this year the highest level of graduate unemployment since the war will certainly force all new science graduates to explore careers outside the confines of their discipline.

P. J. FARAGO

Astrochemistry

Geochemical Exploration of the Moon and Planets. By I. Adler and J. I. Trombka. Vol. 3. Pp. x+243. (Springer-Verlag: Berlin and New York, 1970.) 58 DM; $16.

This book represents an attempt to review past and present efforts to determine the geochemical composition of the Moon and planets. It is essentially concerned with the techniques of geochemical exploration and, as such, could have been given a more specific and informative title. That it contains a fairly extensive review in its 239 pages cannot be denied; however, the organization of this review leaves much to be desired.

The book is arranged, or more accurately, is arbitrarily divided, into six chapters. The first chapter is an introduction which briefly summarizes some of the scientific problems to be solved by exploration of the Moon and planets. The next chapter is entitled "Instruments Used for Compositional Exploration", and describes the instrumentation and experimental results of the Surveyor, Ranger and early Luna spacecraft. The third chapter, "Instruments and Techniques under Development", contains much of the meat of the book in terms of the range of techniques discussed. The authors describe experimental arrangements developed, and being developed, to carry out chemical analysis of the planets using X-ray spectroscopy, X-ray diffraction, neutron activation and mass spectrometry in surface experiments, and X-ray, γ-ray, α-particle and infrared spectroscopy in orbital experiments. The fourth chapter, "Apollo Surface Missions and the Lunar Receiving Laboratory Program", is concerned with the analysis of the returned lunar samples. Presumably because of the breadth of the overall programme, the discussion is restricted to describing NASA's Lunar Receiving Laboratory programme. This is done in unnecessary detail and makes very tedious reading. For example (when describing the Gas Analysis Laboratory), "This laboratory is located on a mezzanine above the Vacuum Laboratory on the third floor of the LRL". The whole chapter, including a description of the preliminary results of Apollo 11, seems to have been taken, with minimal editing or reorganization by the authors, from NASA reports. The fifth chapter, "Data Processing and Analysis", discusses in some detail the problems of data acquisition and analysis from remote environments. The final chapter, "Orbital and Surface Exploration Systems after Early Apollo", discusses a number of projected integrated missions incorporating and extending the techniques discussed earlier.

It is inevitable that much of the book will be rapidly outdated by events in the fast changing field of space exploration. Unfortunately, the way the book is organized accentuates this problem, and in reading it I found myself constantly thinking of how the arrangement of topics could have been improved to make something of more lasting value. The authors do not seem to have set out with a well defined purpose for the book, and this is probably its major flaw. As an honest-to-goodness reference manual of current techniques for space exploration, it is too diffuse. The discussions of scientific results are also scattered about the book and of necessity too cursory to be of any value. As a historical record it suffers from the fact that much of the record is of projected experiments.

People seeking an introduction to the techniques of remote geochemical exploration may find this book useful. They will not find that it has the polish of a good textbook. Perhaps that is too much to expect of an up-to-date review.

GRENVILLE TURNER

Search for Spectra

The Spectra and Structure of Simple Free Radicals. By Gerhard Herzberg. Pp. xi+226. (Cornell University: Ithaca and London, June 1971.) £5.25.

THE 1968 Baker lectures at Cornell University by Gerhard Herzberg, now published in this slim volume, fulfil the ambition of the author to write an introduction to molecular spectroscopy. Few would argue that he is the greatest exponent of the subject still in active research, and on the basis of his three comprehensive books one might suppose that anything he does not know about molecular spectroscopy is not worth knowing.

The book has a title and a sub-title: an introduction to spectroscopy. The latter gives a better representation of its character because free radicals are used only to illustrate general features of molecular spectroscopy and little emphasis is placed on any unique features. In fact the definition of radical which has been adopted ("any species with a short life in the gas phase under normal laboratory conditions") would not be generally accepted in other branches of chemistry. For example, the molecule C_2 is included but not NO. The omission of detailed discussion of electron spin resonance makes the title slightly inappropriate.

The introductory chapter covers some of the special problems that arise in the measurement of the spectra of transient species, although the book as a whole has a theoretical rather than an experimental approach to the subject. There is an enjoyable account of the search for the spectrum of CH_2 which was stimulated by the observation in 1941 of some unidentified lines in the spectrum of a comet. These were finally assigned to molecule C_3 but CH_2 was eventually tracked down in 1961 in the flash photolysis of diazomethane.

The main part of the book is divided into three sections: diatomics, linear polyatomics and non-linear polyatomics. As an indication of the level of the book, the diatomic chapter gives an account of rotation–electronic coupling, the symmetry properties of rotational levels, of Hund's coupling cases *a* and *b* (but not the less important cases) and the rotational structure of electronic bands. It can therefore be seen that the book goes much further than is usual in undergraduate spectroscopy texts.

The chapters on polyatomic radicals give very good accounts of vibronic interactions (the Renner and Jahn–Teller effects) and of vibration–rotation interactions (Λ doubling and Coriolis interaction). There is also an extensive discussion of molecular orbital correlation diagrams and their relevance to the understanding of state symmetries and molecular shapes.

Finally the book is completed by a short chapter on radiationless processes: dissociation, predissociation and recombination. A description of the mechanism of these processes is given and a discussion of selection rules, but no reference has been made to the recent work on predissociation line widths which has been undertaken in several different laboratories.

The book has been elegantly produced and is a pleasure to read. It is a pity that it is so highly priced, as it should be widely used as a textbook for graduate courses in spectroscopy.

J. N. MURRELL

Chemical Mutagenesis

Chemical Mutagenesis in Mammals and Man. Edited by F. Vogel and G. Röhrborn. Pp. xiv+519. (Springer-Verlag: Berlin and New York, 1970.) 124 DM; $34.10.

VARIOUS expert committees have recently emphasized the critical need for mutagenicity testing of chemicals before their registration for commercial or other uses. These committees include the Task Force on Research Planning in Environmental Health Science, March, 1970; the Food and Drug Administration Advisory Committee for Protocols on Safety Evaluation, Panel on Reproduction Studies in the Safety Evaluation of Food Additives and Pesticide Residues, December, 1969; and the Advisory Panel on the Mutagenicity of Pesticides, the Secretary's Commission on Pesticides and their Relationship to Environmental Health, December, 1969. Such recommendations not only reflect critical concerns as to the public health implications of chemical mutagenesis, but also the recent development of a variety of test methods, data from some of which have a high degree of presumptive human relevance.

Chemical Mutagenesis in Mammals and Man is the first of several recent books addressed to this problem with particular emphasis on the importance of *in vivo* mammalian systems in testing for chemical mutagens. This book is a compilation of papers presented at a symposium held on October 7, 1969, in Mainz, Germany. The editors, Drs Vogel and Röhrborn, are admirably qualified for this purpose, as they are internationally recognized and respected workers in the respective fields of population genetics and mutagenicity testing in mammals.

The book contains thirty chapters by authors who include many well known authorities in chemical mutagenesis, including Barthelmess, Ehling, Kuhlmann, Legator, Malling, and Chu. Most chapters deal comprehensively with the specifics of mutagenicity testing in mammalian systems. The editors have also contributed chapters on genetic monitoring of human populations and on the dominant lethal assay in rodents, and also a very useful summary. The stylistic heterogeneity of the book, which the editors have wisely preserved, makes for dynamic and stimulating reading.

The editors are to be warmly congratulated for their timeliness in publishing this volume, which will be of great value, not only to research workers in the field, but also to the chemical and pharmaceutical industries, and to government agencies.

SAMUEL S. EPSTEIN

Designing Libraries

New Library Design: Guide Lines to Planning Academic Library Buildings. By Stephen Langmead and Margaret Beckman. Pp. ix+117. (Wiley: Toronto and Chichester, August 1971.) £5.75.

THE ideas for this book came from the authors' collaboration as project architect and systems librarian for the McLaughlin new library building at the University of Guelph, Canada. They have subsequently acted as consultants to several other Canadian libraries and they lecture in library architecture at the Graduate School of Library and Information Science at the University of Western Ontario. Experience taught them that there are certain steps fundamental to the planning process which are ignored at peril and others which, while not absolutely essential, greatly smooth the passage of a plan through its various stages. In consequence they have set down a systematic schedule of steps to be taken from beginning to end of the planning of a large university library. The resulting guidelines enable anyone planning a new academic library to identify the problems which will need to be solved, make it quite clear who will need to be consulted and why, and provide many of the factual details and most up-to-date accepted standards which both architect and librarian will need. As an illustrative example the McLaughlin Library and its planning brief are described, with added diagrams and photographs.

This must surely be a classic case of joint consultation, the very antithesis of the Columbia Law Library which was described as "reflecting, by its symmetry and balance, the triumph of the Architect over the Librarian". Here the librarian takes his proper place as a qualified person who is well able to organize and administer the extremely complex functions of a modern library intent on communication as well as conservation, who understands the needs of faculty and students, and who controls a management system which designs and evaluates his services. The architect is a professionally competent adviser, planner, designer, coordinator, cost estimator, arbitrator and supervisor. The two clearly respect each other's contribution. The library design favoured is a completely flexible modular plan, flexibility being carried to the point of specially designed handling equipment which can move a fully loaded bookstack.

There is nothing essentially new about library design in the book. The novelty exists in putting it all down on paper so concisely and usefully to produce a book which will take an immediate place as a standard text.

W. Ashworth

Processing Pictures

Picture Language Machines. Edited by S. Kaneff. (Proceedings of a Conference held at the Australian National University, Canberra, February 24–28, 1969.) Pp. xiv+425. (Academic: London and New York, December 1970.) £4.50.

Although the title of this book reflects an overall concern for some general understanding of what would characterize an acceptable picture processing system, individual papers span a variety of topics. The collection starts with four reviews, by Narasimhan on picture languages, Bobrow on question–answer systems, Clowes on a layman's guide to Chomsky, and Jacks on design principles for an industrial graphics system. Then jackets are taken off and the fun begins. The general effect of the book is that of a broadside. Away with the restrictive attitudes of classical pattern recognition with its naive hope for classification based on independent feature extraction. In with the view that any picture processing system worthy of its salt must come to grips with the full range of deep problems associated with systems which can bring to bear an open ended corpus of knowledge about depicted domains to the interpretation of what is depicted. It is this last theme, aspects of which are referred to as "an ability to appropriately articulate structure" (paraphrasing Clowes) and an "ability to use models which are isomorphic to those of the human interacting with the system" (paraphrasing Stanton) which is emphasized in various forms in different papers. It is this theme which motivates the inclusion of the particular review papers and also interesting papers on topics such as natural language behaviour, the role of learning in picture processing, and on dynamic data structuring.

Several stimulating discussions have the theme of the desirability of problems posed by picture processing systems which would make use of descriptions to generate appropriate and different algorithmic behaviour in different contexts.

I found the collection heavy going, largely because of the prolix style of many of the authors—why use a phrase when a paragraph will do? By contrast, the unedited discussions at the end of each paper have an Alice in Wonderland flavour, but like Alice they are sometimes remarkably rewarding.

Nevertheless, given that one is not reading to obtain answers but rather to seek for sensible questions, and those not just about picture processing, the book is well worth the effort involved in reading much of it two or three times.

E. W. Elcock

Flying Mammals

Biology of Bats, Vol. 1. Edited by William A. Wimsatt. Pp. xii+406. (Academic: New York and London, December 1970.) £11.65.

Biology of Bats, Vol. 2. Edited by William A. Wimsatt. Pp. xv+477. (Academic: New York and London, January 1971.) £12.15; $26.

Every biologist secretly believes that his "group" is underrated by the scientific community which fails to appreciate the variety of its forms, the beauty of their adaptations and the importance of the problems posed. Those who study bats are of course quite different: they know their subjects get a raw deal. One has only to analyse any general zoology text or university course: bats fly and thus have unique skeletal modifications (differing from those of pterodactyls and birds) and most use echolocation to catch insects (the rest eat fruit). But whoever quotes a desert bat in an essay on water regulation?

The reasons for all this are quite simple. In addition to the irrational popular repugnance or indifference due to lack of confrontation, there is a natural reluctance to tackle the large and diffuse literature. The lack of a general account of bat biology has been remarkable. Allen's excellent monograph of 1938 was republished, unaltered twenty-four years later and still seems to be in demand after a third of a century. Yet its treatment is semi-popular and necessarily superficial; more recent texts, in German and French, are even shorter.

The deficiency is now being made good by a treatise, edited by William Wimsatt, of which two volumes are now published. It would be unfair to try to assess the scope of the work at present—a third volume and possibly a fourth are planned but no information is yet available on their probable contents. One can only hope at this stage that current omissions will be made good when the work is complete. The present two volumes contain seventeen essays by twelve authors, all American and all authoritative. Each volume carries an introduction by the editor, who has not yet contributed to the text, and detailed author and subject indices. They are beautifully produced, with copious illustrations of high quality, except for some old engravings which have not reproduced well, and one diminutive pair of X-ray photographs.

The first volume has ten chapters on a wide variety of topics and they are necessarily very variable in length. The first and longest chapter, on bat origins and evolution by Jepsen, deserves special mention. It contains a more detailed description of *Icaronycteris index* (the oldest and most complete fossil bat) than has hitherto been published and is illustrated by numerous superb stereo photographs. For many workers this material alone will justify the purchase of this volume. In addition the author gives a general discussion of the Chiroptera that forms an excellent introduction to the whole treatise. The general taxonomy of the order has not changed since Miller (1907), but Jepsen adds some stimulating ideas on relationships. He also argues that flying and gliding make different demands on the body so that bats could never have been gliders.

The second chapter is on karyotypic trends by Baker, and then follow three chapters by Vaughan, giving detailed descriptions of the skeletal and muscular systems respectively, and a discussion of flight patterns and aerodynamics. This last is surprisingly brief although new work is known to be in hand. The remaining five chapters are diverse. Orr writes on development, prenatal and postnatal, giving only two and a half pages to prenatal aspects, which will presumably be expanded later under reproduction. Griffin reviews migration and homing, Davis discusses hibernation ecology and physiological ecology and Lyman deals with thermoregulation and metabolism, but not the metabolic and thermal problems of active flight. Finally Rosenbaum gives a detailed comparative account of the urinary system.

The second volume, although longer, contains only seven chapters, all but the last being closely related. Quay, writing on the integument and its derivatives, mentions, but does not describe, the elaborate and varied facial structures. Sensory aspects of the skin lead naturally into the central nervous system, discussed by Henson, the peripheral nervous system (Quay), the ear and audition (Henson), vision, olfaction and taste (Suthers) and finally to a brief account of the pineal by Quay. Other endocrine aspects will presumably follow later. The volume concludes with an enormous consideration (131 pages) of bats in relation to human health. While no one, least of all those who work with living bats, should doubt the importance of this subject, its place in this volume and the mystery about future plans suggest poor coherence in the whole work.

But for the rest we must (and will eagerly) wait and see. I have high hopes and whatever the outcome one thing seems certain: that the current increase in work on bats, which has occurred in spite of the lack of a book of this sort, will gain much impetus now that it has appeared. DAVID PYE

Character and Attitude

Character Structure and Impulsiveness. By David Kipnis. (Personality and Psychopathology: a Series of Monographs, Texts and Treatises.) Pp. xi+133. (Academic: New York and London, March 1971.) $7.95; £3.75.

Attitude and Attitude Change. By Harry C. Triandis. (Wiley Foundations of Social Psychology Series.) Pp. xiii+232. (Wiley: New York and London, April 1971.) £3.50 boards; £1.65 paper.

THE first of these books reports a series of interrelated studies, all based on the author's scale of impulsiveness, a scale which correlates both with Gough's socialization scale and the extraversion scale of the MPI. The scale concentrates on masculine outdoor hobbies, and all studies are therefore wisely limited to male subjects. Kipnis starts with the interesting and important idea that diagnostic instruments in psychology should be used like diagnostic tests in medicine, that is not only to describe the current state of a person but to show how to improve the score of those with a deficit on the test.

After a series of studies designed to establish the validity of his instrument he implements this action-orientation in the following way: high scorers on impulsiveness are underachievers in college examinations; they are also highly motivated by material incentives. Kipnis, accordingly established an ingenious field experiment with proper controls, in which impulsive underachievers were paid money for doing their mathematics course. The results show that the more intelligent impulsive students improved their grade in this condition, which had, however, no effect on the less intelligent. Although the role of intelligence as a moderator of other personality predispositions is interesting, it receives no theoretical treatment in this book, which is altogether deficient on theory. Furthermore, the effect disappeared when payment stopped. The intended "cure" may, for all one knows, only have strengthened the original "illness". Here, as elsewhere, nothing would have been more practical than a good theory to deal with such doubts.

The study of attitudes continues to dominate social psychology and social psychological publications. At least a dozen books on attitude and attitude change have been published during the past year. Triandis's contribution—*Attitude and Attitude Change*—is in the textbook category. As one would expect from this author, it is workmanlike, clearly written and thoroughly up-to-date. The text is refreshingly catholic in approach and goes beyond the currently most fashionable debate about consistency theories. Instructors and students will find the student assignments at the end of each chapter particularly useful; they are imaginative guides to self-instruction and encourage students to think about the underlying assumptions in attitude research. There is a bibliography of well over five hundred items. MARIE JAHODA

Quantum Text

Practical Quantum Mechanics I. By Siegfried Flügge. (Die Grundlehren der Mathematischen Wissenschaften in Einzeldarstellungen, Band 177.) Pp. xiv+341. (Springer-Verlag: Berlin and New York, 1971.) 70 DM; $20.30.

Practical Quantum Mechanics II. By Siegfried Flügge. (Die Grundlehren der Mathematischen Wissenschaften in Einzeldarstellungen, Band 178.) Pp. xii+287.) (Springer-Verlag: Berlin and New York, 1971.) 60 DM; $17.40.

ANYONE who has taught a course of quantum mechanics knows the difficulty of providing practical examples which are within the mathematical competence of the students and can be completed in a reasonable time. In these two volumes, which have been designed as a unified work, will be found 219 problems, together with their solutions, which will greatly extend the repertoire. They are all of moderate length and will be accessible to any student who can recognize the Bessel equation and consult references for properties of its solutions when these are required.

The first volume deals exclusively with one-body problems without spin. Many one dimensional and three dimensional potentials are introduced and the problems of calculating wavefunctions for bound states and for elastic scattering are well represented. Applications are made to some specific situations in atomic and nuclear physics, with numerical values given to all the constants so as to emphasize the order of magnitude of the effects. The problems illustrating scattering resonances and Regge poles are especially welcome. In the second volume the problems cover a wider range and include illustrations of the introduction of spin, the interactions between two and three particles, quantum statistics and the Dirac relativistic equation with shorter sections on non-stationary problems and radiation theory. It will be very useful to have problems on tensor forces, the Tietz approximation in Thomas–Fermi theory and on helicity. Between the two volumes most of the features of elementary quantum mechanics which have to be compared with the corresponding features of classical mechanics are introduced and discussed.

Faced with so many useful problems and elegant solutions I am reluctant to turn to the limitations of this collection. It has to be said, however, that the problems are all of textbook type and deal with the solution of the differential equations for the wavefunctions and the subsequent calculation of properties. The classical techniques of mathematical analysis are emphasized. Matrix techniques, which are often better illustrations of real problems and are extensively used in modern self-consistent field treatments of atoms and molecules, scarcely appear and there is no group theory. The diagram techniques of modern perturbation theories appear briefly in only one solution. As an introduction to the practical problems of quantum theory and to the most used mathematical methods this is a very lopsided and unrepresentative compilation. As a preparation for courses on specialized aspects of quantum theory probably the examples on nuclear theory will be considered most adequate. The student interested in atomic and molecular physics, in field theory or in solid state physics will find few examples that he cannot find elsewhere.

The volumes have been well produced with many well designed graphs. The English style has some reminders of the German of the earlier edition, but the book has been rewritten. The purist will object to the abbreviation of "having no complete set of eigenvectors" to "having no eigenvectors" in some matrix problems.

For the teacher who selects carefully and can supplement from other sources, this will be a valuable and much used addition to the armoury. For the unaided student who learns best by working out examples and attempting open-ended problems the practical introduction to quantum mechanics still has to be written. G. G. HALL

CORRESPONDENCE

Tolerable Pollution

SIR,—I have read with great interest Dr Samuel S. Epstein's article entitled "Control of Chemical Pollutants" (*Nature*, **228**, 816; 1970). Many of the points made by Dr Epstein are very well taken and need emphasis. Unfortunately, however, some of the concepts that he expresses need to be examined more closely and carefully thought through.

For instance, in the determination of "efficacy" the practising physician may have entirely different concepts than the academician who is not dealing with patients on a daily basis. To the academician there is probably no place for a placebo. To the harassed physician trying to bring solace to the whining, complaining patient the placebo may have a most important, though limited, role. I remember clearly a female patient I once had of 70+ years who demanded of me a "tonic". "Tonics," it should be remembered, were practically a part of the culture of people in this age range. Finding no "tonics" in the formulary of the hospital where I was working, I prescribed an innocuous "bladder mixture" made up of potassium iodide and hyoscyamus. Much to my surprise, the patient returned at her next visit lauding the "efficacy" of this "tonic" to the skies and insisted that it be renewed. Obviously this was not a material that I should be permitted to market as "Dr E's famous tonic", but was there any harm in its use in these circumstances? Who, then, is to determine efficacy? Should flavours, colours, antirancidity materials or other such materials be permitted in foods? Do they have "efficacy"? Some might well argue that foods should be eaten only with their natural inherent flavours and colours and that the addition of artificial (or even natural) flavours or colours does not improve the food's efficacy. Rancid food should simply be thrown out. What about the present uproar over the use of tolbutamide in diabetics? Even cyclamates are thought by many physicians to have value in the treatment of obesity and diabetes. Who is to make these important determinations?

Turning to the concepts of carcinogenicity, teratogenicity, and mutagenicity, there are few people who do not believe that we should control them to the best of our ability. However, as I pointed out in my Ramazzini oration (*J. Occ. Med.*, **13**, 161; 1971), the concept of zero is a mathematical one. As our analytic techniques become more and more sensitive, it will ultimately be necessary for us to establish a "practical" zero. In essence this will mean that some finite, measurable quantity will be determined to be "tolerable". Thus a "tolerance" for carcinogens, teratogens, and mutagens will be established. Precedence for this approach has been established in the milk and water sanitation fields. Here a definite number of organisms are allowed, that is, are considered tolerable. It was recognized that to set the levels at zero organisms could well have eliminated these essentials from human consumption. Thus recognizing the impracticality of the so-called Delaney clause and devoting research efforts to a serious attempt to establish tolerances for carcinogens seems a more sensible approach than simply extending this concept to teratogens and mutagens. This approach has been taken by Truhaut and an international committee in attempting to establish a tolerance for aflatoxins in foods.

Lastly, the concept of "disinterested" scientists needs carefully to be examined. What, truly, do we mean by a "disinterested" scientist? Is he "disinterested" because he is an academician? After all, Pasteur made what is probably one of the most important discoveries to mankind when he was working for the French wine industry. Is the scientist directly engaged in or dependent for support from a federal bureaucracy "disinterested" in its perpetuation? Can a scientist's views be modified as he lives longer and becomes more mature and knowledgeable? Is this change in viewpoint due to his having lost his disinterested status?

The concepts I expressed in my editorial on environmental carcinogenesis (*Cancer Res.*, **22**, 395; 1962) seem today to need re-emphasis. We do need to control *significant* exposures of the general population to carcinogens, teratogens, and mutagens. After all, today we do not have any real comprehension of what the teratogenic or mutagenic rates are in the human race as a whole. For all we know, these rates may be on the downswing now because of man's ability to overcome some of the vicissitudes of his former existence. A rereading of the "Report on the Sanitary Condition of the Labouring Population of Great Britain" by Edwin Chadwick, 1842 (edit. by M. W. Flinn, Edinburgh University Press, 1965) should reassure us on the real progress we have made in just a little over 100 years. We still, nonetheless, live in a real world, fraught with real and imminent dangers which we must do our best to minimize in a real and practical way.

Yours faithfully,

Obituary

Wendell Meredith Stanley

WENDELL MEREDITH STANLEY, Professor of Molecular Biology and of Biochemistry at the University of California, Berkeley, died suddenly, aged 66, on June 15 in Spain.

His career in biochemistry and molecular biology began at the University of Illinois in 1926 when, as a graduate student of the organic chemist, Roger Adams, he synthesized a series of fatty acids and correlated their structures and physical properties with effectiveness against the leprosy bacillus. After earning his PhD degree in 1929, Stanley went to Germany as a National Research Council Fellow in the laboratory of Professor Heinrich Wieland, where he worked on sterols of yeast. Returning to the United States in 1931, he worked for a year at the Rockefeller Institute for Medical Research in New York with cell physiologist W. J. V. Osterhout, on model chemical systems that simulated cell membranes.

In 1932, Stanley moved to the Rockefeller Institute Laboratories in Princeton, New Jersey. There he began his studies on the chemistry of viruses which culminated in 1935 with the crystallization of tobacco mosaic virus (TMV), the first of these disease agents to be obtained in such a form. Not content with the isolation and crystallization of TMV, he proceeded with a small group of colleagues to develop systematically and imaginatively an entirely new field of science: the biology, chemistry, and physics of viruses. From these efforts, and work elsewhere, the chemical composition and morphology of a variety of viruses were defined in molecular terms. Stanley's initial studies on the chemical modification of viruses later provided the foundation for inactivating viruses for vaccine production and for studies on molecular

genetics. With the onset of the Second World War, his group turned to animal viruses and their fundamental studies on the purification and characterization of influenza virus led to the preparation of a safe and effective vaccine.

Stanley joined the University of California at Berkeley where, in 1948, he founded the Virus Laboratory and built a new Department of Biochemistry which he served as Chairman until 1953. Subsequently he initiated the formation of the Department of Virology in 1958 which he chaired until 1964 when it was expanded to become the present Department of Molecular Biology. In these academic departments, Stanley promoted and fostered the blending of teaching and research in a most fruitful way. His own interests were directed toward the conquest of viral diseases and the potentialities of viruses in the induction of cancer. He encouraged research in this area and exerted considerable influence in programmes on the national level. His contributions to cancer research were recognized by two awards from the American Cancer Society, one in 1959 and another in 1963 and by his selection as President of the Tenth International Cancer Congress, Houston, Texas, in 1970.

Many honours came to Stanley over the years: elections to honorary societies, distinguished lectureships, about a score of honorary degrees, and numerous medals and prizes including the Nobel Prize in Chemistry in 1946. In his lifetime, he had three different and equally productive careers: first as a bold, imaginative scientist whose research revolutionized biological thought; second as an outstanding educational administrator who recruited, supported and inspired many young scientists; and third as a distinguished statesman who played a major role in shaping enlightened national and international policy with regard to scientific research on cancer and the role of viruses.

British Diary

Monday, September 13

Fundamentals of Software for Computer Engineers (vacation school, thirteen days) Institution of Electrical Engineers, in association with the Institution of Electronic and Radio Engineers, at the University of Manchester.

Surface Chemistry of Oxides (three-day Discussion) Faraday Society, in the Chemistry Department, Brunel University, Uxbridge, Middlesex.

Tuesday, September 14

5th Annual Solid State Devices Conference (three days) Institute of Physics and the Physical Society, in collaboration with the Institution of Electrical Engineers, the Institution of Electronic and Radio Engineers, the Institute of Electrical and Electronic Engineers, at the University of Lancaster.

Flexographic Printing Inks (7.30 p.m.) Oil and Colour Chemists' Association, at the Griffin Hotel, Boar Lane, Leeds.

Wednesday, September 15

Centrifugal Methods of Particle Size Analysis (2.30 p.m.) Society for Analytical Chemistry, North East Section and the Particle Size Analysis Group, at Newcastle University, Room L.101, Mertz Court, Queen Victoria Road, Newcastle-upon-Tyne.

Formulation of Two Epoxy Paints (4.30 p.m.) Mr A. McWilliam, Oil and Colour Chemists' Association, at the Manchester Literary and Philosophical Society, 36 George Street, Manchester 1. (Student Lecture.)

Thursday, September 16

Insect/Plant Relationships (two-day symposium) Royal Entomological Society of London, at the Imperial College of Science Mechanical Engineering Lecture Theatre, Exhibition Road, London SW7.

Modern Analytical Techniques for Bio-Active Substances (two-day meeting) Society for Analytical Chemistry, at the University of Surrey, Guildford, Surrey.

Friday, September 17

The Work of the Government Chemist (7 p.m.) Dr H. Egan, Society for Analytical Chemistry, Western Region, in the Chemistry Department, University of Bristol.

Sunday, September 19

Electrical Measurement Practice (vacation school, thirteen days) Institution of Electrical Engineers, in association with the Institution of Electronic and Radio Engineers, at the University of York.

HOW TO BUY NATURE

Volumes start in January, March, May, July, Septembe and November, but subscriptions may begin at any time.
The direct postal price per subscription is:
12 MONTHS* (52 issues per title)

NATURE Volume 233
SEPTEMBER 17 1971

Reform by Inches or Half-inches

It is still an open question whether the British Association for the Advancement of Science will manage to survive the years ahead. The steps taken at the Swansea meeting of the association two weeks ago (see *Nature*, **233**, 80; 1971) to modernize the administration of the association are steps in the right direction, but they are manifestly small and even timid steps. There is a chance that the association's management might have moved even more cautiously if it had not been for the unaccustomed toughness of the voluntary committees, sixteen or so of them, which are responsible for the detailed arrangement of the programme of the association's annual meeting. From all appearances, even the heart-searching of the past year, which has at least seen the production of a fearless analysis of the association's financial and intellectual plight (see *Nature*, **231**, 412; 1971), seems not to have created a sufficient sense of urgency. The result is that the Swansea meeting was presented not with a tangible programme of reconstruction but with an invitation to appoint yet another committee to put flesh on the bones of the proposals put forward by the Committee of Review three months ago. The danger, of course, is that the association's claim on public attention, like its investment income, is being drained away with the passage of each week or month.

Why is the association making such heavy weather of its attempt to stay in business? Gone, it seems, is the robust independence of the early nineteenth century, when the British Association came into being (in the year in which the First Reform Bill was being fought through the British Parliament) because its founders recognized the need of an independent and even irreverent forum for interdisciplinary discussions. (Those were bad times for the Royal Society, which might otherwise have done the job.) Only a part of the reason lies in the intricacy of the association's constitution, with its complicated hierarchy of committees intended chiefly to ensure that responsibility lies nowhere identifiable. There is also a serious danger that the association is quite unreasonably imprisoned by conventions which belong to the second half of the nineteenth century, not the first.

The pomp and ceremony which attends each annual meeting, and which must leave a good many of those who went to Swansea hanging their heads in shame, is one obvious sign of this symptom of the association's trouble. Is it really necessary that the first item on each year's programme, increasingly intended to be a means of provoking public discussion of important issues, should consist of a solemn procession in which academics and would-be academics dress up in academic finery and make their way like actors in a bad Greek chorus through a public auditorium to a platform more often used by actors than by participants in a ceremony for awarding honorary degrees? Is it really in keeping with the association's wish to perform a real service in the modern world that there should be yet another procession to the local cathedral to hear some bishop deliver himself of familiar pronouncements on the place of science in society at large? And even if good fellowship (of which there is plenty) must be acknowledged to be an important part of the association's annual rites, is it really necessary that there should be so many invitations for men and women to dress up in evening clothes? Harmless though these conventions may be in ordinary circumstances, an organization seeking to make a mark on public opinion as well as on the opinions of its members must necessarily use its public ceremonies as ways of reinforcing what it has to say. Especially because it is a long time since the association had constructive and sharp things to say about issues of public importance, nobody should be surprised that it has acquired a public reputation much more appropriate to a snobbish and old-fashioned club than to an organization seeking to enhance the public reputation of modern science in a modern and sceptical world.

What is to be done? The first need is that the association should form a clear vision of what it wants to be. If, as seems entirely proper, one important objective is the encouragement of an informed opinion on public issues with scientific antecedents or connexions, the association will have to work out ways of defining what these issues are and what needs to be said about them. This is intellectual work, not simply administration, which means that devices will have to be developed for containing controversy within the framework of the association. If the association is to play a creative part in the encouragement of European collaboration in science, as Professor W. H. McCrea and Sir Brian Flowers (see page 173) have been urging, then it will have to become more professional in organization and more imaginative in innovation. If the association wishes, as it should, to go on providing stimulating intellectual fare for those who turn up at its annual meetings, there is a case for strengthening, not for eroding, the voluntary organization of the association into sections of specialists which has provided the pattern of the past century. It is a great surprise that the Committee of Review, responsible for the past year's self-examination, has done so little to follow up the suggestion that stronger links should be forged between the British Association and the more conventional learned societies.

But is it worth the trouble? This is what a great many British scientists will be asking. That they do so is a measure of how, over the years, the association has lost its hold on the interests and affections of professional scientists in Britain. Luckily, however, there is still enough support to ensure continuity, at least for another year or two. Moreover, it is now more clear than ever that there is a public need for what the association might accomplish. Rarely has the profession of science been as widely misunderstood and wrongly maligned than at the present time; the British Association could help enormously to set the record straight, not so much by means of counter-propaganda as by the objective study of important public issues on which public opinion seems commonly to founder. This is a task which is almost by definition beyond the scope of the orthodox societies. It is also one that cannot be left to an organization such as the British Society for Social Responsibility in Science—that has become such a vigorous pressure group that it cannot be a sounding board for informed opinion at the same time. It is earnestly to be hoped, in the critical months ahead, that professional scientists in Britain will recognize that the fate of this distinguished and potentially valuable institution will depend on their help—or at least on their indulgence.

Opportunities for Collaboration in Europe

In spite of all the enthusiasm for European collaboration that has become common in the sphere of the British Government's influence, very little has been done to show how the institutions responsible for the support of scientific research should be adapted to meet the future needs. Although the imaginative declaration by Sir Brian Flowers at the British Association last week (reprinted in full on page 173 of this issue) is necessarily a first attempt to list the jobs that must at some stage be done, it is encouraging that serious public discussion has at least begun. The question now is what should be done to advance the cause, and to make the prospect of European collaboration a reality. It goes without saying that the first essential is to recognize that in the long run, the creativity of the European scientific community is potentially of inestimable value.

The first thing to be said is that European collaboration in science will not yield its full potential until the university systems of Western Europe are much more closely integrated with each other than at present. There is no point in beating about this bush. At some stage, it will be necessary to ensure that centres of research will be easily accessible to all who work in their fields of excellence. In many cases, this implies that universities should be able to appoint to their faculties people of foreign nationality simply on the strength of their potential contribution to research and teaching. Elsewhere, research institutes will have to be similarly accessible. There are obvious difficulties when systems of higher education are administered as if they were parts of the government, as in France or Italy, but it will probably be much more difficult to arrange that research institutes, most of which are supported by public money, will be similarly accessible. When, for example, will the *Centre Nationale de la Recherche Scientifique* be allowed by the government of France to take on its payroll scientists from elsewhere? In the same spirit, when will the British government agree that the Agricultural Research Council (if it survives the report of the Rothschild Committee) should employ scientists from France or the Netherlands? The Commission of the European Communities has made some progress, in the past few months, towards the definition of rules for regulating the transfer of professional qualifications from one European country to another, but this is a far cry from the arrangements that will eventually be necessary for allowing foreign participation in institutions which are traditionally regarded as national in their essentials.

Beyond that hurdle is the problem of what should be done to rationalize—"to harmonize" as they say in Brussels—the pattern of basic research in Europe. In the past few years, there have been notable successes in collaboration in fields such as high-energy physics, and there is no doubt that CERN is a model of how nations can function in such a way that their collective efforts are more valuable in combination than separately. It is only proper to recall that in the past few years, there have been failures as well as successes. Sir Brian Flowers has done a public service in asking that schemes for collaboration should be designed in a spirit of realism and not with the hope of extraneous benefits. The failure of ELDO shows what is likely to go wrong when institutions are designed to bring political rather than technical benefits, but it is also a great misfortune that, more recently, European nations have made very little headway in collaboration on the construction of large telescopes. But if a sensible coordination of plans is as difficult as this in fields in which there are expensive and conspicuous instruments to be built, what prospect is there for cooperative planning in less spectacular fields of inquiry?

The obstacles are obvious and formidable. The past few years have shown how carefully the Science Research Council in Britain has had to move in its attempts to mould the pattern of research at British universities. It is easy enough to persuade universities and other research organizations to accept that there can be only a few centres of excellence in any field, but the same institutions, however enlightened, are usually unwilling to accept that laudable attempts to concentrate research at selected centres should deprive them of what they consider to be their rights. Some countries on the mainland—France, for example—are better able to work out patterns for the conduct of research because of their centralized systems of support, but elsewhere—as in West Germany—the machinery for the channelling of public money to basic research is an awkward blend of centralized direction and decentralization, with the universities only accidentally involved in the conduct of research. In short, European institutions for the administration of the public money spent on basic research are such an inhomogenous group that structural considerations will impede coordination. To begin with, the best that can be hoped for is that the governments of Europe will establish some kind of talking shop within which research councils, public research foundations and universities can begin to work out what needs to be accomplished. Quite independently of whether the European Community is to be enlarged, this is a task that could be attempted right away.

Further away is the problem of how money should be spent on European research. For the time being, at least, it is to be expected that the member nations of the European Community will regard what they spend on higher education and basic research as a long-term investment in national well-being or even prosperity. Their justification for this expenditure will often rest on the belief that such expenditure will improve their competitive position within the communities With luck, in other words, natural rivalry should help to ensure that European governments spend generously on higher education and basic research in the decade or so ahead. But this is bound to be a passing phase. As soon as there emerges a rational pattern of research, it will also be necessary to work out ways of coordinating expenditures of funds. That will be the point at which governments with large budgets for research and higher education will be looking askance at those who drag their feet. At the same time, it will be necessary for governments (and taxpayers) to accept that national resources should be spent on foreign enterprises. At this stage, it is hard to see how governments can be prevented from tearing each other to pieces without an international budget for research and higher education. The fact that such a goal is bound, at present, to seem distant should not allow those who administer public expenditure on research and development to shy away from the fact that the planning must be done now, and not shelved until some future date.

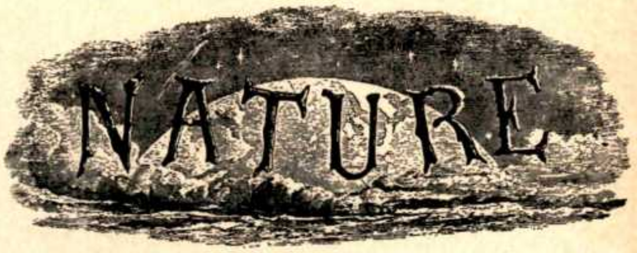
From Prayer-meeting to Trade Fair

THE fourth United Nations Conference on the Peaceful Uses of Atomic Energy, now finishing at Geneva, is a remarkable proof of how rapidly it has been possible to convert a bright idea into a workable and sophisticated technology. It is also a powerful demonstration of the way in which technological innovations should be introduced to those most likely to benefit from them with a greater sense of sobriety than that attending the first United Nations conference in 1955. Will the sponsors learn the lesson now staring everybody in the face?

Fifteen years ago, nuclear power was still largely military in character. The first United Nations conference was remarkable for the way in which it helped the governments of the nuclear powers to put some of their secret cards on an open table. Even such facts of nature as the cross-sections of nuclear reactions involving neutrons were secret, and it seemed at the time to be a great discovery for all concerned that measurements on both sides of what was then called the Iron Curtain tended to be roughly in agreement with each other. To be sure, it was at the time a puzzle to know just why the nuclear powers had decided to make a partially clean breast of the information which they had acquired in the pursuit of military objectives. Perhaps they were responding honestly to the complaint of non-nuclear nations that it would be intolerable if the Great Powers were able to hang on to what seemed to be a monopoly in the exploitation of an important and beneficial technology. It may be that the initiative of President Eisenhower, who launched from the United States an international programme with the slogan "Atoms for Peace", struck a genuine response from the Soviet Union and the United Kingdom. It may even be, as the sceptics were inclined at the time to protest, that all concerned had their eyes on the main chance—the opportunity for making important sales of equipment. In any case, there is in retrospect no doubt that the promise of nuclear energy was spelt out with too much enthusiasm, and that in the process the development of the industry was hindered and not helped. The moral is that in the launching of a new technology, as in the launching of a business enterprise, it is imprudent to publish too cheerful a prospectus.

A second lesson to be learned from the past two weeks at Geneva is that technical progress in nuclear power has been as rapid as anybody could realistically expect. Fifteen years ago, even thermal reactors were entirely novel. Only the foolhardy talked seriously of fast reactors. Although there has since been all kinds of false excitement about fusion reactors, it does now seem as if thermonuclear power is about to be a reality. The importance of this development cannot be exaggerated—it is tantamount to freedom from anxiety about energy supplies in the foreseeable future. That makes up for all kinds of errors.

100 Years Ago



THE preparations made by the Governments of the present age to have every phase of a total eclipse studied and recorded, contrast favourably with the superstition that prevailed a few centuries ago. For instance, the *Scientific American* quotes the following from a German paper :—"The Elector of Darmstadt was informed of the approach of a total eclipse in 1699, and published the following edict in consequence :—'His Highness, having been informed that on Wednesday morning next at ten o'clock a very dangerous eclipse will take place, orders that on the day previous, and a few days afterwards, all cattle be kept housed, and to this end ample fodder be provided ; the doors and windows of the stalls to be carefully secured, the drinking wells to be covered up, the cellars and garrets guarded so that the bad atmosphere may not obtain lodgment, and thus produce infection, because such eclipses frequently occasion whooping cough, epilepsy, paralysis, fever, and other diseases, against which every precaution should be observed.'"

OLD WORLD

BRAIN DRAIN

The Circus Leaves Town

QUIETLY, without any fuss, the North American Joint Selection Board has ceased to exist due to the withdrawal of the Civil Service Commission (CSC). The board, comprising representatives of the CSC, the United Kingdom Atomic Energy Authority (UK AEA) and the Central Electricity Generating Board (CEGB) toured North America to recruit the best of the young British research scientists and engineers who had emigrated as part of the Brain Drain, and wanted to return.

Established in 1958 (the CEGB joined in 1962) under the chairmanship of Mr Harry Hoff, the board—which became known to applicants as Hoff's Circus—saw its job not as a mission to reverse the Brain Drain but as an attempt to recruit the best people to carry out research work in Britain.

The Civil Service Commission has now withdrawn because it feels that the operation "is no longer cost effective" and because at the moment it is finding "the calibre and quantity of recruits required" in Britain. As the costs do not diminish proportionately because one of the parties has withdrawn, the UK AEA and CEGB have decided not to continue. Costs have risen rapidly despite attempts to cut them to a minimum by introducing a greater degree of preselection of candidates. In the board's 1968 report it was estimated that the cost was "about £500 per man recruited—scarcely any more, if not less, than the cost of recruiting a comparable man in the United Kingdom". The exact figure for last year is not known, but it was in the region of £1,000–£1,200 per man.

The UK AEA and CEGB are not particularly distressed to see the board go, although both would have been happy for it to continue. With postgraduate jobs hard to come by both are getting plenty of applicants. On the other hand, whereas there is no suggestion that all the brightest graduates go abroad, there is no doubt that the standard of the recruits from America, with their extra year or two of experience was very high. Sixty or seventy per cent of those interviewed were recommended for appointment but as can be seen from the table less than 20 per cent were actually placed.

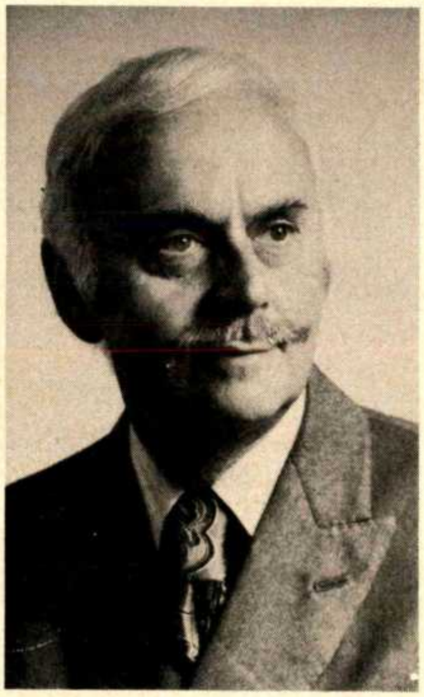
Success of the North American Joint Selection Board 1966-71

Year	Applied	Interviewed	Placed
1966–67	—*	215	39
67–68	—	249	47
68–69	—	257	36
69–70	250	173†	30
70–71	302	186	>25‡

* Figures not known
† Preselection introduced
‡ Final figure not yet known

Until recently it looked as if the board's activities were about to expand. The Post Office was interested in joining and for the past two years information about suitable applicants has been passed on to British Rail and the British Steel Corporation.

But if the board's members no longer need recruits from America, there are still many British subjects in America who would like to return home. The number of applicants has been increasing over the years and Management Selection Ltd (MSL), who provide information and advice to both applicants and employers, say that, if anything, there are more scientists wanting to return. The problem for the exile is that whereas one interview with the board allowed him to be considered for several posts in Britain, he now has to come to this country at his own expense in the hope of finding a job when he gets here. It is ironic that just when the employment situation for highly qualified scientists in this country is very difficult, one of the organizations that made it easier to find a research job has ceased to function.



Photograph by Mark Gerson, FIIP, ARPS

Mr Harry Hoff of the UK AEA, Chairman of the North American Joint Selection Board throughout its thirteen year life.

Companies (and the board members) are perfectly willing to consider the exile for research posts in Britain, but recently the demand for highly qualified people has fallen away, and the companies are finding that by and large they, too, are finding the quantity and quality they want in Britain, and only when they are sure that an applicant from North America is suited to the post are they prepared to pay the fare for the applicant to attend an interview in Britain.

Now that the Brain Drain is no longer a subject for popular concern it is interesting to note that with the employment situation for PhDs becoming increasingly difficult in North America (see *Nature*, **233**, 87; 1971) more Americans are inquiring at MSL about job possibilities in Britain. Seems like the end of a chapter.

MOLECULAR BIOLOGY

EMBO not for Culham

THE decision by the British government not to offer Culham as a site for the proposed European Molecular Biology Organization (EMBO) laboratory last week caused less surprise in scientific circles than it did in the ranks of the Oxfordshire County Planning Committee.

The decision is only one more chapter in the lengthening history of the laboratory. Although conceived in 1963 when EMBO was first formed, no final decision has yet been taken on whether the laboratory will be built but this is expected to be recommended by an international conference next month.

Britain is only one of the countries to consider offering a site for the laboratory and the eventual decision not to do so was taken according to the Department of Education and Science, because "the sites being proposed by West Germany offered better facilities and climate" than the Culham site. In the 1967 proposal for the laboratory it was stated that the site must be in distinguished intellectual surroundings, be easily accessible, have good amenities in terms of climate, housing, international schools, language and countryside, and the revised proposals in 1970 emphasized the need for the laboratory to be near a large research centre in which sophisticated instrumentation and computation are being developed for other purposes. Mr Hugh Farrant, chairman of the Oxfordshire Planning Committee which had welcomed the proposal of Culham as the site last year, claims that apart from the stipulation about climate, the Culham site fills the bill, having adequate communications and being close to both Oxford and Harwell.

The considerations that led to the decision probably included the fact that Germany is prepared to put considerably more money into the project than any of the other governments involved and has two suitable sites to offer, at Munich and Heidelberg, which are both in the centre of Europe. A further consideration is that Dr John Kendrew of the Medical Research Council's Molecular Biology Laboratory at Cambridge is the likeliest candidate to become the first director of the proposed laboratory and a British director of a European laboratory in Britain would not appear very European.

Mr Airey Neave, MP for Abingdon, who described the decision as "rather disappointing" is to ask Mrs Thatcher, Secretary of State for Education and Science, for a full statement, but as the decision was taken after full consultation with EMBO officials it is unlikely to provide ammunition for the dissenters.

COMMUNICATIONS

Dial Around the World

THE largest single contract ever awarded by the British Post Office has been given to Plessey Telecommunications for the first stage of Britain's newest international telephone exchange. The exchange will use crossbar switching and will provide more than a third of the 18,000 international telephone circuits eventually planned to be handled by the Post Office's new Mondial House, now under construction. As part of the contract, worth about £10 million, Plessey will also provide a complex of computers which will perform the complicated accounting procedures involved in international telephony—the cost of each call must be apportioned among the countries of its origin, its destination and its passage. The same equipment can, at the same time, give precise information on how the exchange is routing the calls presented to it.

For the Post Office, the opening of the exchange in Mondial House at the end of 1973 will mean a larger increase in the number of destinations to which British telephone subscribers can dial their own telephone calls. Until this year, the Post Office depended on its exchange at Faraday House, with its 2,000-circuit capacity to handle all international calls. The Wood Street international exchange has now began to operate and will eventually have a capacity of 8,400 circuits. But when Mondial House's 18,000 circuits are available, there will be connexions, by means of cable, microwave and satellite, to 51 countries, including 29 in Europe as well as the United States, India and Australia. As the number of countries which can dial each other increases, thanks largely to satellites, Britain's importance as a transit centre will increase—and so will the Post Office's revenues from external telecommunications.

For Plessey, the award is a reminder that the Post Office has fully repented of its error of the 1950s when it vetoed the crossbar switching system with which the United States, Sweden, Japan and some continental countries were modernizing their telephone networks. Plessey (or the company which it has since absorbed, Automatic Telephone and Electric) developed crossbar privately, without a Post Office subsidy. Only in recent years has Plessey persuaded the Post Office to adopt it as a standard exchange.

Plessey has also developed the newer kind of exchange described as electronic but actually based on reed relays—which the Post Office is also installing. The system is called TXE-2 and the Post Office eagerly publicizes the gradual introduction of electronic exchanges into the telephone network. But Plessey executives last week made it plain that only crossbar, and not the much-publicized TXE-2 switch, could handle a telephone exchange of the size and complexity required by Mondial House.

Considering Plessey's position as British developer of crossbar it was unlikely that the contract would go to the Post Office's other major suppliers, GEC-AEI and Standard Telephones and Cables. Plessey can probably be fairly confident of supplying the rest of the Mondial House exchange. But the Post Office may not always buy British. It is showing a new boldness in accepting foreign suppliers and gave Philips of Eindhoven a much-prized contract for an international telegraph switching exchange just a few weeks ago. Plessey received this big Mondial House contract fairly easily but neither it nor the other two manufacturers can afford to be complacent about the future.

NUCLEAR PHYSICS

Cause for Concern?

CONCERN is growing among nuclear structure physicists in Britain that the proposed national nuclear structure facility will absorb all the finance available for nuclear structure research and that the facilities now available at the universities will be declared obsolete with a consequent withdrawal of Science Research Council support.

Sir Brian Flowers, chairman of the Science Research Council, said last week that when the national facility is built all other accelerators in the country will be outdated and that support would be withdrawn from several of these facilities in order to concentrate on the new machine. In particular, Sir Brian mentioned that the Heavy Ion Linear Accelerator at Manchester University and the Tandem Van de Graaff at Liverpool University would be among the first to have their support cut whereas the most recent accelerators at Oxford University would still be supported. It would all depend, he said, on the nuclear structure budget at the time at which the national centre became operational. Sir Brian emphasized that the matter is now in a state of flux and that nothing definite would emerge until a decision was taken on the national facility; this will probably be in eighteen months' time when the design study team, at present at work at Daresbury, have completed their work (see *Nature*, **232**, 76; 1971).

K. W. Allen, professor of nuclear structure at Oxford University, said this week that it was unreasonable and unthinkable that support for the Oxford accelerators would be withdrawn and that such a decision would be contrary to current policy. The Oxford accelerators are at present supported to the tune of £250,000 a year, but there is no question of this being withdrawn before 1976, the earliest date for completion of the national facility if the green light is given soon.

Scientists at Liverpool are also concerned about the future of their laboratory but they are understandably less worried than the Oxford physicists. Although no final decision has been taken by the SRC on the siting of the national facility, the fact that the design study team is sited at Daresbury tips the scales in favour of a site in the north of England. Daresbury is within easy reach of both Liverpool and Manchester and if funds are withdrawn from both these universities they can still effectively carry on their research. But the position of the Oxford physicists and others farther away from the site is not so cheerful.

Enthusiasm for the nuclear structure centre will undoubtedly wane in some quarters if, on completion of the design study, there is a possibility of closing down all other facilities in favour of the new centre. If this happens, future developments in nuclear structure in Britain will have to turn in some other direction. One possibility is the upgrading of the Oxford accelerators by replacing the 12 MeV tandem Van de Graaff with a more powerful version (see *Nature Physical Science*, **232**, 76; 1971). Such a proposal is under consideration and if the SRC supports this improvement it will possibly signify the beginning of the end for the National Nuclear Structure Facility project.

TECHNOLOGY

Innovation Research

THE smaller member countries of the Organization for Economic Cooperation and Development, such as the Netherlands, Sweden and Switzerland, have been very successful in reaping the benefits of technological innovation. That is one of the conclusions to be drawn from an extensive international review of research on the processes and mechanisms of technological innovation published recently by the OECD (*The Conditions for Success in Technological Innovation*, OECD, Paris; 1971).

The aim of the report is partly to assess how member countries of the OECD have measured up to technological challenges and partly to discover how an increasingly favourable climate for innovation can be created. Some of the conclusions of the report, such as the idea that industrial competition is vital to successful innovation, are, however, still matters of contention which are unlikely to be resolved because of a lack of data. More than half of the 155 accounts of research cited in the report are concerned solely with the United States and the report calls not only for more research in other member countries of the OECD but also for further investigation of particular aspects of the problem, such as the mechanisms of technology transfer between industries and the time scales involved in innovation processes.

The OECD report follows closely on the heels of a British report by the Centre for the Study of Industrial Innovation (see *Nature*, **232**, 432; 1971) which analysed the reasons for the abandonment of technological projects; before that, for example, there was the report of the Charpie committee to the US Department of Commerce which highlighted, possibly to an unrealistic extent, the importance of small companies in the innovative process.

The latest study is intended as a sequel to the series of reports called *Gaps in Technology* and published by the OECD during the past few years. The innovation process is considered from the point of view of industry, government and the universities—the three principal components of the framework in which innovation takes place. Important relationships seem to exist between companies of differing sizes because, for example, small companies tend to specialize in sophisticated technological areas which require smaller production capacity but which often make use of the experience of scientists and engineers who once worked in large industrial (or government) laboratories. The mobility of scientists should be encouraged, says the report, because it accelerates the diffusion of technology and brings fresh minds to bear on particular problems. Industrial management also faces many problems of adjustment to an ever-changing situation but these can be overcome if entrepreneurial attitudes are encouraged, not only in individual managers but also in whole companies and institutions so that information can be exchanged easily across organizational boundaries and changes made quickly and efficiently as the situation demands.

The report also suggests that governments can contribute to the improvement of the innovation process through changes in the tax and patent systems and that government procurement will continue to play a vital role in improving the technological prowess of industry.

Miscellaneous Intelligence
